Migeotte's analysis³⁷. (The values have been converted to a standard set of intensity units to facilitate comparison.) The R10 line was also used by Nielsen and Migeotte³⁷ but, to our knowledge, there have been no more recent determinations of its intensity. Except for Fink *et al.*³⁹ results for R0, the newer intensity values are all considerably larger than those reported by Goldberg *et al.*³⁸, but there is considerable scatter in the measurements. A higher intensity for R0 of 0.0143 cm⁻² atm⁻¹ at 298 K has also been derived by J. S. Margolis (personal communication) from a preliminary analysis of new Kitt Peak laboratory spectra of the 2ν₃ band. As an additional check, we have analysed the R0 line in a Kitt Peak solar spectrum recorded with a zenith angle of 49.37° on 10 November 1981. To obtain a CH₄ tropospheric mixing ratio of 1.60 p.p.m.v., an intensity value of 0.0147 cm⁻² atm⁻¹ at 296 K is required, again considerably larger than the Goldberg *et al.*³⁸ intensity. If the Fink *et al.*³⁹ results are excluded, the average of the newer laboratory determinations is 1.40 times larger than the Goldberg *et al.*³⁸ values. Simply scaling the Nielsen and Migeotte³⁷ column amounts by the inverse of this factor produces a CH₄ vertical column amount of 1.49 × 10¹⁹ molecules cm⁻², corresponding to a CH₄ tropospheric mixing ratio of 1.14 p.p.m.v. The same intensities³⁸ were used by Goldberg⁴³ to analyse infrared solar spectra recorded from Lake Angelus, Michigan (elevation 296 m), and from Mt Wilson, California (elevation 1,750 m), in 1949–1950. If the same scaling factor for the intensity error is adopted along with the case B profile shape, we determine values of 2.28 × 10¹⁹ molecules cm⁻² and 1.17 p.p.m.v. and 1.85 × 10¹⁹ molecules cm⁻² and 1.15 p.p.m.v. for the CH₄ vertical column amount and tropospheric mixing ratio above Lake Angelus and Mt Wilson, respectively. These revised values for the ~1950 CH₄ tropospheric mixing ratio are in excellent agreement with the result of our detailed analysis of the Jungfraujoch spectra, but they should be regarded as subject to a large uncertainty because of the scatter in the intensity values reported for the 2ν₃ band. It is interesting to note that a gas chromatographic analysis of air in the troposphere in 1951 indicated a CH₄ mixing ratio of between 1.1 and 1.2 p.p.m.v.^{44,45}, in excellent agreement with our results.

Conclusions

The major finding reported in this paper, that historic solar spectra indicate a significantly lower concentration of CH₄ (1.14 p.p.m.v.) in 1951, has important implications for the fol-

lowing reasons: (1) the result extends the historic baseline of atmospheric measurements of CH₄; (2) the results reported here are consistent with a global increase of atmospheric CH₄ of 1.1 ± 0.2% yr⁻¹ from 1951 to 1981, assuming a constant rate of increase over this period. This suggests at least a 30-yr increase in atmospheric CH₄, a significantly longer time increase than previously reported, based on atmospheric measurements. It is interesting to note that the average CH₄ increase of 1.1 ± 0.2% yr⁻¹ from 1951 to 1981 reported here is comparable with the annual CH₄ increase deduced from several years of continuous gas chromatograph measurements in the late 1970s and early 1980s; (3) the earlier reported higher values of CH₄ deduced from ground-based infrared solar spectra^{37,43} can be significantly lowered using improved spectroscopic parameters; (4) the atmospheric lifetime of CH₄ is long (~7 yr) compared with the 1–2 yr required to mix a species uniformly throughout both hemispheres⁴⁶. Hence, a single measurement of CH₄, as reported here, is characteristic of its global concentration. Therefore, our measurement has important implications for the global budget of CH₄. The 30-yr increase of methane reported here may be caused by an increase in the global production rate of CH₄ (which includes anaerobic decomposition of organic matter, enteric fermentation in ruminants, biomass burning and natural gas leakage), a decrease in the global destruction rate of CH₄ (which is controlled by the reaction of CH₄ with the hydroxyl radical OH), or a combination of both^{47,48}. The implications of the Jungfraujoch spectra-deduced concentration of CH₄ and other trace radiative-active species and their impact on global species budgets and on the photochemistry of the atmosphere will be discussed in an accompanying paper⁴⁹.

We thank D. J. Richardson for help with the digitizing of the Jungfraujoch solar spectrum and S. A. Motley for assistance in locating a copy of the Jungfraujoch solar atlas and the many references used in this study. We also thank J. W. Brault and G. M. Stokes for the Kitt Peak solar spectra and P. Hachler for communicating the Swiss meteorological data for 1951; R. K. Seals Jr, J. M. Russell III and J. D. Lawrence Jr for useful discussions and encouragement; and S. A. Penkett for pointing out the analysis of the chemical composition of tropospheric air performed by E. Gleuckauf at Harwell in the early 1950s. The interferometer in the NSO on Kitt Peak is operated by the Association of Universities for Research in Astronomy, Inc., under contract with the NSF. T.M. is a NASA-MRC Research Associate.

Free tropospheric carbon monoxide concentrations in 1950 and 1951 deduced from infrared total column amount measurements

Curtis P. Rinsland & Joel S. Levine

Atmospheric Sciences Division, NASA Langley Research Center, Hampton, Virginia 23665, USA

Published total vertical column amounts of carbon monoxide deduced from infrared solar spectra recorded during 1950–51 in the Swiss Alps have been reanalysed based on improved spectroscopic parameters for CO and a curve of growth. From a comparison of the 1950–51 results and modern measurements, an average increase of ~2% per year in the free tropospheric concentration of CO above Europe is estimated for 1950–77.

CARBON monoxide (CO) was discovered by Migeotte in the Earth's atmosphere by its absorption signature in infrared, ground-based spectra of the Sun¹. (Migeotte² also discovered methane (CH₄) using the same technique.) Carbon monoxide is an important species in the photochemistry of the troposphere. The reaction between CO and the hydroxyl radical (OH), the dominant oxidizing species in the troposphere, controls the global destruction of both of these species. The reaction between these two gases accounts for more than 80% of the global destruction of OH and the total destruction of CO, and the reaction between CO and OH which produces an atom of hydrogen (H) may also lead to the photochemical production of ozone (O₃) in the troposphere³.

Measurements indicate that at ground level, the mixing ratio of CO is between 120 and 200 parts per 10⁹ by volume (p.p.b.v.) in the Northern Hemisphere compared with 40–60 p.p.b.v. in the Southern Hemisphere³. The surface mixing ratio of CO is higher than in the free troposphere, at least for the Northern Hemisphere³. Measurements in the Northern Hemisphere indicate the background level of CO varies by about a factor of two with season^{4,5}, with a seasonal maximum in CO of about 150 p.p.b.v. in early spring and a seasonal minimum of about 70 p.p.b.v. in late summer at Cape Meares, Oregon, a remote site at 45° N (ref. 4).

There have been several recent studies on the possible temporal change of CO mixing ratios in the troposphere. Khalil and Rasmussen⁴ found a long-term increase of about 6% yr⁻¹ based on 44 months of continuous Cape Meares data (1979–82). Analyses of two other CO data sets by the same authors also indicate a long-term increase in tropospheric CO. The first of these two other CO data sets is unpublished and was obtained at Cape Grim, Tasmania (42° S) between October 1981 and April 1984. These results suggest that CO may be increasing by about 4% yr⁻¹ in the Southern Hemisphere. However, we note that Seiler *et al.*⁷ have compared Southern Hemispheric CO mixing ratios measured in 1971–72 with CO mixing ratios measured continuously at Cape Point (34° S) between 1978 and 1981 and conclude that Southern Hemisphere CO mixing ratios could not have changed by more than 5–10% over the past decade. Measurements of the total column amount of CO have been deduced from infrared spectroscopic measurements recorded between 1970 and 1982 (excluding a gap in the measurements between 1977 and 1980) in the Soviet Union^{8–11}. The reanalysis by Khalil and Rasmussen⁶ of the data reported by Dvoryashina *et al.*⁸ suggests that CO may have increased by 2% (±1%) yr⁻¹ since 1974, but there is no evidence for an increase in CO prior to 1974. The long-term increase of tropospheric CO suggested by some of these studies^{4,6} is very important and may indicate a significant anthropogenic perturbation to tropospheric composition and/or chemistry. Of equal importance is the conclusion that the long-term CO increase is not apparent in the measurement records in the Soviet Union prior to 1974.

As emphasized in these studies^{4,6}, it is very difficult to separate

the relatively small systematic long-term trend in background CO concentration from the large seasonal cycle and fluctuations in concentration caused by seasonal variations in CO production, destruction, and transport. For this reason, it is desirable to have continuous measurements from a remote site spanning several decades. Although no such database exists, we believe that important information on the long-term trend in CO concentration can be deduced from analysis of historic solar spectra. Since atmospheric concentrations of CO are difficult to store in containers¹², historic solar spectra may represent the only record of early CO concentrations. A number of infrared solar spectra obtained in the early 1950s show prominent telluric lines of CO and have been analysed for total CO column amounts^{13–16}. With the exception of the study by Benesch *et al.*¹³, these spectra were recorded near large urban areas, which are significant sources of CO.

The Benesch *et al.*¹³ measurements are unique in that they were obtained from spectra recorded at a remote, clean-air, high-altitude observatory in the Swiss Alps. We have previously analysed spectra obtained more than three decades ago at the same site to deduce the tropospheric CH₄ level¹⁷. In this article, we reanalyse the early CO column amount measurements of Benesch *et al.*¹³ using modern spectroscopic parameters and obtain estimates of the free tropospheric volume mixing ratio of CO above Europe on 9 days in 1950–51.

Measurements and analysis

The solar spectra analyzed by Benesch *et al.*¹³ were recorded at the Jungfraujoch Scientific Station in the Swiss Alps (46.5° N, 8.0° E, altitude 3,578 m) on three days in August 1950 and on six days between April and September 1951. The observations were recorded with a Pfund-type prism-grating spectrometer and with a Perkin-Elmer thermocouple as a detector. The instrumentation has been described in detail^{18,19} and a number of the spectra have been published in a solar atlas²⁰, including measurements which show prominent CO absorption lines on 25 April 1951 and 7 June 1951. Most of the spectra analyzed by Benesch *et al.*¹³ are unpublished.

Benesch *et al.*¹³ determined total vertical column amounts of CO (in units of cm-atm at STP) from measurements of the equivalent width of the R3 line of the (1-0) vibration-rotation band of ¹²C¹⁶O at 2,158.300 cm⁻¹. The column amounts were derived assuming that the absorption of the R3 line in the solar spectra occurs in the square root region of the curve of growth. In the square root region, the equivalent width W is given by^{15,21}

$$W = 2(Sb_L Lu)^{1/2} \quad (1)$$

where b_L is the Lorentz half-linewidth at absorption half height, S is the line intensity per molecule, L is Loschmidt's number, and u is the absorber column amount in units of cm-atm at STP. Equation (1) assumes the equivalent width has been obtained from an integration of the absorption over all frequen-

Table 1 Comparison of line parameters at 296 K for the R3 line of the (1-0) band of $^{12}\text{C}^{16}\text{O}$

Parameter	Units	Benesch <i>et al.</i> ¹³ Value	Present study	
			Value	Ref.
S	cm^{-1} molecule	2.91×10^{-19}	3.47×10^{-19}	Chackerian <i>et al.</i> ²²
b_L^0 (CO-air)	$\text{cm}^{-1} \text{ atm}^{-1}$	0.046	0.0672	Nakazawa & Tanaka ²⁴
n		0.0	0.75	Varanasi ²⁶

cies. The halfwidth b_L is related to the halfwidth per atmosphere b_L^0 at reference temperature T_0 by

$$b_L = b_L^0 \left(\frac{T}{T_0} \right)^{-n} p \quad (2)$$

where T is the temperature in K, p is the pressure in atm, and n is the coefficient of the temperature dependence of the halfwidth. Benesch *et al.*¹³ assumed the air-broadened halfwidth to be independent of temperature ($n=0$).

A recent comprehensive survey of the literature shows a large number of measurements of intensities and collisional broadening parameters for the 1-0 band of $^{12}\text{C}^{16}\text{O}$ (ref. 21). From these results, we have attempted to select the most accurate parameters for the R3 line. The adopted values converted to the standard reference temperature of 296 K are listed in Table 1 along with those assumed in the Benesch *et al.*¹³ analysis. The $^{12}\text{C}^{16}\text{O}$ line intensities of Chackerian *et al.*²² have a quoted absolute uncertainty of $\pm 3\%$. We multiplied the Chackerian *et al.*²² intensity for R3 by 0.98652 to account for the concentration of $^{12}\text{C}^{16}\text{O}$ in natural CO (ref. 23). The air-broadened halfwidth b_L^0 (CO-air) assumed in this study was calculated from the experimental halfwidths of Nakazawa and Tanaka²⁴ assuming the relation

$$b_L^0(\text{CO-air}) = 0.79 b_L^0(\text{CO-N}_2) + 0.21 b_L^0(\text{CO-O}_2) \quad (3)$$

where $b_L^0(\text{CO-N}_2)$ and $b_L^0(\text{CO-O}_2)$ are the experimental N_2 - and O_2 -broadened halfwidths, respectively. We note that the Varghese and Hanson²⁵ N_2 -broadened halfwidth for R3 agrees within 4% with the Nakazawa and Tanaka value²⁴ and that the calculated air-broadened halfwidth agrees closely with the value of $0.0695 \pm 0.0036 \text{ cm}^{-1} \text{ atm}^{-1}$ at 300 K determined for air-broadening by Varanasi²⁶.

Benesch *et al.*¹³ assumed an effective temperature of 230 K and an effective pressure of 0.3 atm for the CO molecules above the Jungfraujoch station. If these values are also adopted as a first approximation, the column amounts u_B derived by Benesch *et al.*¹³ can be compared to column amounts u_R determined with the revised spectroscopic parameters. Substituting the values from Table 1 into equations (1) and (2), we find for a given measured equivalent width that

$$\frac{u_R}{u_B} = 0.475 \quad (4)$$

Hence, by assuming values that are too low for both the R3 intensity and halfwidth, Benesch *et al.*¹³ overestimated the CO column amount above the Jungfraujoch station by about a factor of 2.

More accurate corrections to the Benesch *et al.*¹³ values have been obtained from a curve of growth derived from equivalent widths measured from synthetic spectra calculated with a 17-layer atmospheric model. Table 2 presents the pressure-temperature and CO reference mixing ratio profile assumed in the analysis. The pressures and temperatures are density-weighted values calculated from the 1976 US Standard Atmosphere²⁷. The reference CO mixing ratio profile adopted in the analysis is based on midlatitude Northern Hemisphere measurements. The stratospheric portion of this profile is taken from a set of reference gas concentration profiles²⁸ and is based on the measurements of Fabian *et al.*²⁹ and Ehhalt and Tönnissen³⁰. Below 11 km, a constant mixing ratio of 130 p.p.b.v. has been assumed based on an approximate average of free tropospheric measurements over Europe, although the actual measurements exhibit a wide scatter around the average value, as shown in

Fig. 10 of Logan *et al.*³. A Voigt profile has been assumed for the CO line shape.

Our spectral simulations indicate that the R3 CO line is slightly blended with a feature due to N_2O and solar CO on the low wavenumber wing and a feature due to N_2O on the high wavenumber wing. Also, the R3 line contains a contribution due to the absorption by the same transition in the solar atmosphere. Because the blends on both wings of the line were marked in the solar atlas²⁰ and identified in the list of measures³¹, we have assumed that Benesch *et al.*¹³ corrected their measured R3 line equivalent widths for both telluric and solar line absorption by these blending transitions. Therefore, only telluric absorption by the R3 line was included in our curve of growth calculations. The revised parameters in Table 1 were assumed along with the position and lower state energy from the 1982 Air Force Geophysics Laboratory line parameters compilation³².

The CO volume mixing ratio profile in Table 2 corresponds to a vertical column amount of 0.0512 cm-atm STP. To determine the curve of growth, a sequence of 10 synthetic spectra were calculated by scaling this mixing ratio distribution by multiplicative factors ranging from 0.1 to 2.4. Each spectrum has been convolved with a gaussian instrument function having a width corresponding to the resolution of the Jungfraujoch measurements as given in Table 1 of the solar atlas²⁰. Because of significant pressure broadening in the troposphere, absorption in the line wings is important in determining the total equivalent width. Since Benesch *et al.*¹³ did not discuss corrections to their equivalent widths for the contribution from the line wings, we assume their values were derived from integrating over only a finite wavenumber interval. From examination of the published solar spectra in this region^{13,20} and our calculated synthetic spectra, we estimated their integration limits to have been 2,157.5–2,159.1 cm^{-1} . Outside of this interval, absorption by the R3 line changes slowly with wavenumber and is overlapped by absorption from other lines in the Jungfraujoch solar spectra. We adopted these integration limits in analyzing the synthetic spectra and determined the background (measured 100% transmittance level) from a least-squares fit to data within 0.1 cm^{-1} of the integration limits. The derived equivalent widths are fairly insensitive to the adopted integration limits. For example, if the

Table 2 Atmospheric parameters assumed in the analysis

Layer boundaries (km)	Temperature (K)	Pressure (mbar)	CO mixing ratio (p.p.b.v.)
3.578–5.0	260.4	595.3	130
5.0–7.5	247.9	461.2	130
7.5–9.0	234.7	345.1	130
9.0–11.0	224.2	267.3	130
11.0–14.0	217.3	184.2	72.5
14.0–17.0	216.6	115.1	35.0
17.0–20.0	216.6	71.9	18.8
20.0–22.0	217.6	47.9	15.5
22.0–24.0	219.5	35.1	16.5
24.0–26.0	221.5	25.8	17.5
26.0–28.0	223.5	19.1	18.5
28.0–30.0	225.5	14.1	19.5
30.0–32.0	228.4	10.4	21.0
32.0–35.0	233.3	7.35	23.5
35.0–40.0	242.5	4.33	29.2
40.0–60.0	260.0	1.55	30.0
60.0–100.0	230.7	0.11	30.0

integration range is decreased to 2,157.6–2,159.0 cm^{-1} , the equivalent widths determined from the synthetic spectra decrease by 0.8–2.1%. An increase in the integration range to 2,157.4–2,159.2 cm^{-1} increases the calculated equivalent widths by 0.6–1.7%. As expected, the largest changes in equivalent width were found for the calculations with the largest CO profile multiplicative scaling factor.

For each of the 11 measurements reported by Benesch *et al.*¹³, a revised total vertical column amount and a corresponding free tropospheric volume mixing ratio of CO were derived from the curve of growth using the following steps:

- (1) The solar zenith angle was estimated from the date and approximate time of observation (listed in Fig. 5 of Benesch *et al.*¹³).
- (2) The CO column amount was calculated from the product of the secant of the solar zenith angle and the reported total vertical column amount.
- (3) From this result and the line parameters assumed by Benesch *et al.*¹³, the measured equivalent width was estimated using equation (1).
- (4) A revised CO column amount was derived from this equivalent width using the curve of growth.
- (5) The revised vertical column of CO was calculated by dividing the revised CO column amount by the secant of the solar zenith angle. The corresponding volume mixing ratio below 11 km is assumed to be the free tropospheric mixing ratio of CO for that date and time.

The revised total vertical column amounts and corresponding free tropospheric volume mixing ratios of CO are given in Table 3. For comparison, the total vertical column amounts of CO deduced by Benesch *et al.*¹³ are also listed. On the average, the revised values are 59% of the Benesch *et al.*¹³ column amounts. This result is slightly higher than the 47.5% estimate obtained from the simple scaling procedures discussed previously.

As a check on our curve of growth results, the region in the Jungfraujoch solar atlas²⁰ containing the R3 line of CO was analysed using the revised set of CO line parameters (Table 1) and the technique of nonlinear least squares spectral curve fitting. These spectral data were recorded at about 6:30 UT on April 25, 1951, corresponding to a solar zenith angle of 69.3° (measurement no. 5 in Table 3). Solar CO lines in the region were included in the fitting procedure as described by Rinsland *et al.*³³; otherwise, the analysis method was the same as that used to determine the 1951 CH_4 tropospheric mixing ratio from the Jungfraujoch solar spectra¹⁷. The fitting results are shown in Fig. 1. The free tropospheric mixing ratio of CO deduced from this spectral analysis is 99 p.p.b.v., somewhat lower than the value of 110 p.p.b.v. obtained from the curve of growth analysis for the same measurements.

It is also important to be sure that the mixing ratio results do not depend on the line selected for the analysis. Therefore, the spectral fitting procedure and a similarly revised set of CO line parameters have been applied to the analysis of the spectral

Fig. 1 Comparison between a solar absorption spectrum recorded at the Jungfraujoch Scientific Station on 25 April 1951 (solid line) and least-squares best-fit to the data (crosses). The measured spectrum was obtained about 6:30 UT at a solar zenith angle of 69.3° and has been normalized to the largest measured intensity in the fitted region. The residuals (observed minus calculated) are plotted at top.

interval containing the P14 line at 2,086.322 cm^{-1} and the P15 line at 2,082.002 cm^{-1} . These data were also recorded on 25 April 1951. The value of 103 p.p.b.v. determined from this analysis is in good agreement with the values obtained from the spectral fitting and curve of growth analyses of the R3 line (cited above).

The CO volume mixing ratios in Table 3 range from 30 to 110 p.p.b.v., a factor of 3.7 to 1, indicating large variability in CO abundance (the extreme limit of 4.4 to 1 deduced by Benesch *et al.*¹³ is reduced slightly by curve-of-growth effects). Although most of this variability is probably real, some of the scatter in the measurements is likely to be due to changes in the altitude of the tropopause (a constant value of 11 km has been assumed), errors in the equivalent width measurements of Benesch *et al.*¹³, and errors resulting from the assumption of a standard atmosphere pressure-temperature profile in the analysis. It is interesting to note that Benesch *et al.*¹³ observed significant changes in the CO total vertical amount on time scales of several hours. They were unable to find a meaningful correlation between these variations and meteorological data.

The CO mixing ratios observed on the 3 days of measurement in August 1950 are lower than those observed during August and September 1951 and much lower than all modern measurements of free tropospheric CO near the same latitude. Therefore, we investigated the available meteorological records for unusual conditions, for example very low tropopause altitude or intrusion of stratospheric air during a tropopause folding event. Surface weather maps for the 3 days of observation (J. Tierney, personal communication) show a weak anti-cyclonic circulation pattern near Switzerland with no evidence for the vigorous tropospheric depressions and associated fronts typically observed during a significant intrusion of stratospheric air into the troposphere³⁴. Radiosonde measurements from Payerne (46.5° N, 6.6° E) for 05 h U.T. indicate tropopause altitudes of 10.5 km for 19 August, 13.0 km for 21 August and 12.3 km for 30 August (no radiosonde measurements were made on 20 August, P. Hachler, personal communication), close to the nominal tropopause height of 11 km assumed in our calculations for all dates. However, the conventional temperature lapse rate

Fig. 2 Monthly averaged free tropospheric volume mixing ratios of CO deduced from the 1950–51 Jungfraujoch solar spectra. The number of measurements is shown for each month.

criterion used to define the tropopause altitude may be a poor indicator of the separation of stratospheric and tropospheric air during a major tropopause folding event³⁴. Therefore, potential temperature versus log. pressure plots were constructed, and these do not show the large low-altitude vertical gradients of isentropes characteristic of a tropopause fold³⁴. On the basis of the available evidence we have retained these three measurements in our analysis of the long-term trend, and we find it quite interesting that such very low CO mixing ratios apparently existed in the free troposphere above Europe in 1950.

In Fig. 2, all of the measurements within a given month have been averaged to evaluate the seasonal trend in CO. As can be seen, despite the limited number of measurements, there is some evidence for a seasonal cycle in the 1950–51 CO mixing ratios, with higher values in spring than in late summer and early fall, in rough agreement with modern studies^{4–6}. Unfortunately, the number of measurements and their distribution with season are insufficient and the scatter of the results is too large to define accurately the seasonal cycle of atmospheric CO in 1950 and 1951.

Fortuitously, the Jungfraujoch measurements are distributed at about the times of year when modern Northern Hemisphere measurements^{4,5} indicate the CO concentrations range from their highest values (early spring) to their lowest values (late summer). Therefore, a straight average of the 4-monthly means in Fig. 2 can be used to calculate a seasonally-averaged value with minimal sampling bias. The result is 76 p.p.b.v., a value considerably lower than most published measurements for the free troposphere over Europe (see Fig. 10 of Logan *et al.*³). The estimated uncertainty in the 1950–51 average is rather large (± 25 p.p.b.v.), primarily because of the large inferred variability, the limited number of measurements, uncertainties in the assumed CO vertical mixing ratio distribution (the measurements presented in Fig. 10 of Logan *et al.*³ and the measurements of Seiler and Fishman³⁵ show some evidence for a decrease of CO volume mixing ratio with altitude in the free troposphere), and uncertainties in the revised R3 CO spectroscopic line parameters. The assumptions adopted in the analysis to infer the Benesch *et al.*¹³ equivalent widths also contribute to the uncertainty.

Estimate of long-term (CO) trend

The most accurate estimate of the long-term trend in tropospheric CO concentration would result from comparison of the 1950–51 values with values deduced in the same way from modern Jungfraujoch solar spectra. This procedure would reduce potential systematic errors resulting from uncertainties in the assumed values for the spectroscopic line parameters and the CO vertical mixing ratio distribution and from potential systematic errors resulting from the method of analysis. Unfortunately, no modern Jungfraujoch spectra covering the CO region have been published. Therefore, we have been forced to assume modern CO measurement values from the literature.

Figure 10 of Logan *et al.*³ presents a number of free tropospheric measurements of CO obtained over Europe by Seiler *et al.*³⁶ in November and December 1976 (50–60° N) and by Fabian

*et al.*³⁷ in June and September 1977 (44° N). Near 6 km, the mean altitude of tropospheric CO molecules above the Jungfraujoch station (assuming the reference CO vertical distribution in Table 2), these measurements range from 75 to 175 p.p.b.v. with an approximate average value of 130 p.p.b.v. Measurements^{35,38,39} at other longitudes between 1971 and 1978 show similar average free tropospheric CO mixing ratios near 45° N (see Fig. 10 of Seiler and Fishman³⁵). Assuming an average of 130 p.p.b.v. for 1976–77 and our seasonally averaged mixing ratio of 76 p.p.b.v. for 1950–51, an average rate of CO increase of 2.1% yr⁻¹ is obtained for this 27-year period. Uncertainty in the average rate of increase results from uncertainties in the adopted average values for both 1950–51 and 1976–77. Assuming average values ranging from 115 to 145 p.p.b.v. for the latter period and average values for 1950–51 corresponding to the estimated uncertainty limits, the average rate of CO concentration increase for 1950–77 is calculated from the extremes of the uncertainty limits to be between 0.5–4.1% yr⁻¹.

Conclusions

The major conclusion of this study is that the seasonally averaged free tropospheric mixing ratio of CO above Europe in 1950–51 was 76 ± 25 p.p.b.v., a value considerably lower than most modern measurements for the same location. The deduced average rate of increase in free tropospheric CO above Europe is $\sim 2\%$ yr⁻¹ for 1950–77 and is consistent with more recent measurements of increasing CO concentration at sites in both the Northern and Southern Hemispheres^{4,6}. The primary strength of the present analysis is that the average rate of CO increase has been estimated from measurements separated by 27 years, over which time the small rate of increase in CO concentration has accumulated to a value which allows it to be separated fairly well from short-term fluctuations and the seasonal cycle of CO. Nonetheless, the accuracy in the estimated average rate of increase in free tropospheric CO over Europe is limited considerably by the large variability of CO, as deduced both from our analysis of the limited set of 11 measurements from 1950–51 and from more numerous recent measurements. Because of the large spatial as well as temporal variability of tropospheric CO, the globally averaged rate of change in CO concentration cannot be inferred from our results. However, when the published measurements of increasing CO at both Northern and Southern Hemisphere sites^{4,6} are considered in addition to our results, we believe there now exists considerable experimental evidence for a global increase in tropospheric CO concentration. Some implications of the Jungfraujoch spectra-deduced increases in tropospheric CO and CH₄ are discussed in the accompanying paper.⁴⁰

H. G. Reichle Jr and S. A. Motley helped us locate many of the pertinent papers on tropospheric CO cited in this work. We also thank Thomas Miles for his assistance with the analysis of the August 1950 meteorological data and G. Roland for sending us a copy of the Jungfraujoch infrared solar atlas.

The photochemistry of methane and carbon monoxide in the troposphere in 1950 and 1985

Joel S. Levine, Curtis P. Rinsland & Geoffrey M. Tennille*

Atmospheric Sciences Division and *Analysis and Computation Division, NASA Langley Research Center, Hampton, Virginia 23665, USA

The ~1%/year increase in tropospheric methane and ~2%/year increase in tropospheric carbon monoxide deduced from recent analyses of ground-based solar infrared spectra recorded in 1950 and 1951 have very important implications for the photochemistry and chemistry of the troposphere. Photochemical calculations indicate that as a result of the increase of methane and carbon monoxide since 1950-51, levels of the hydroxyl radical, the key species in the photochemistry of the troposphere, may have decreased by about 25%.

RECENT analyses of ground-based solar infrared absorption spectra recorded in 1950 and 1951 at the Jungfraujoch Scientific Station in the Swiss Alps (46.5°N, 3578 m altitude) have led to the discovery that 34-35 years ago, the mean tropospheric mixing ratio of methane (CH₄) was 1.14 ± 0.08 parts per million by volume (p.p.m.v.)¹ or only about 70% of its present day mixing ratio of 1.65 p.p.m.v. and that the average free tropospheric (~5 km) mixing ratio of carbon monoxide (CO) was only about half of its present day mixing ratio at that latitude². Extrapolating the 1951 data point to the present day value suggests that tropospheric CH₄ has increased at an average rate of about $1.1 \pm 0.2\%$ yr⁻¹ over the past 34 years. This rate of increase in CH₄ is comparable to the 1-2% per year increase in tropospheric CH₄ based on nearly continuous ground-based gas chromatograph measurements obtained since about 1977³⁻⁶, and is consistent with CH₄ levels measured in air bubbles embedded in polar ice cores^{7,8}. Extrapolating the 1950-51 data to present day values at the same latitude suggests that tropospheric CO has increased at an average rate of about 2% per year over the past 34-35 years, consistent with very recent continuous ground-based measurements of CO obtained over a $3\frac{1}{2}$ year period (1979-82)⁹.

In this article, we consider the implications of the 1950 and 1951 measurements on the ground production rates of CH₄ and CO and on the tropospheric photochemical coupling between these two gases. At the outset, it must be emphasized that the troposphere is a strongly coupled chemical system of several dozen interacting species controlled by many different processes, including natural and anthropogenic emissions, photochemical and chemical processes, and various heterogeneous loss processes^{10,11}. There are many deficiencies and uncertainties in our understanding of the composition and chemistry of the present-day troposphere. Trying to understand the composition and chemistry of the troposphere more than three decades ago based on measurements of only two species is very difficult at the least. We know nothing about the concentrations of the other several dozen tropospheric species. While our analysis must be considered somewhat speculative, we believe that the analysis and interpretation of historic solar spectra using photochemical

models offer a new and powerful technique to study changes in tropospheric composition and chemistry over a period of several decades.

Photochemical calculations presented here were obtained with a one-dimensional photochemical model of the troposphere¹²⁻¹⁵. The version of the model used in these calculations contains 80 species from the following species families: hydrogen, nitrogen, oxygen, carbon, ammonia, sulphur and halogen (chlorine, bromine and iodine). The non-methane hydrocarbon chemistry^{13,14} was not included in the present calculations to reduce computational costs. The photochemical production of CO resulting from the oxidation of natural and anthropogenic nonmethane hydrocarbons is included in the surface flux boundary condition for CO, as will be described. The calculation of photolysis rates includes the effect of molecular absorption, Rayleigh scattering, Mie scattering, and surface albedo, based on a detailed radiative transfer model¹⁶ which has been incorporated into our photochemical model. The radiative transfer calculation uses optical depths for ozone absorption, Rayleigh scattering, and Mie scattering¹⁷. A major change in the present version of the model is the inclusion of CH₄ as a chemically active species whose vertical profile is calculated using a continuity-transport equation with a surface flux of CH₄ as the lower boundary condition. In earlier versions of the model, the vertical distribution of CH₄, a long-lived gas, was specified as an input parameter, as it is in almost every tropospheric photochemical model. For present day conditions, the following surface boundary conditions were specified for 45°N latitude: CH₄, upward flux of 1.5×10^{11} molecules cm⁻² s⁻¹ (which results in a surface mixing ratio of 1.65 p.p.m.v., the present-day value); CO, upward flux of 6.0×10^{11} molecules cm⁻² s⁻¹ (see below); NO_x (NO + NO₂), upward flux 5.0×10^9 molecules cm⁻² s⁻¹; HNO₃, downward flux of 1.55×10^9 molecules cm⁻² s⁻¹; and O₃, fixed-number density of 7.5×10^{11} molecules cm⁻³. At the tropopause (10 km), the following non-zero boundary conditions were imposed: NO_x, downward flux across tropopause of 2.0×10^7 molecules cm⁻² s⁻¹; HNO₃, downward flux across tropopause of 1.2×10^8 molecules cm⁻² s⁻¹; and O₃, fixed number density of 1.0×10^{12} molecules cm⁻³. The boundary condi-

tions for NO_x , HNO_3 and O_3 are typical values used in most photochemical models¹⁰.

Methane is produced at the Earth's surface primarily by biological fermentation in anaerobic environments such as wetlands and rice fields; in ruminating animals, mostly cattle; and by biomass burning and natural gas leakage¹⁸. Methane is not produced photochemically or chemically in our strongly oxidizing atmosphere. Carbon monoxide is produced photochemically in the atmosphere via the methane oxidation chain¹⁹⁻²³. The oxidation of methane may be the largest source of CO, and may account for as much as 400–1,000 megatonnes of CO yr^{-1} (ref. 10). CO also results from other natural and anthropogenic activities. The estimated range for other known sources of CO (in units of $\text{Mt}(\text{CO}) \text{ yr}^{-1}$) are: oxidation of natural nonmethane hydrocarbons = 280–1,200; fossil fuel use = 400–1,000; forest clearing = 200–800; savanna burning = 100–400; emissions by plants = 50–200; oxidation of anthropogenic nonmethane hydrocarbons = 0–180; wood used as fuel = 25–150; ocean = 20–80; and forest wildfires = 10–50 (ref. 10). The range for the sum of the above CO sources other than the methane oxidation chain component, is 1,085–4,060 $\text{Mt}(\text{CO}) \text{ yr}^{-1}$ (equivalent to about $2\text{--}6 \times 10^{11} \text{ CO molecules cm}^{-2} \text{ s}^{-1}$). In a recent photochemical study, surface CO fluxes ranging between 1 and $10 \times 10^{11} \text{ CO molecules cm}^{-2} \text{ s}^{-1}$ were used²⁴. In our photochemical calculations for the present-day troposphere, we have assumed a surface CO flux which appears appropriate for 45°N , of $6 \times 10^{11} \text{ CO molecules cm}^{-2} \text{ s}^{-1}$. The Jungfraujoch spectra were obtained at a latitude of 46.5°N , just about the latitude of maximum CO concentration in the troposphere¹⁰. The CO produced via the methane oxidation chain is calculated explicitly as a photochemical production component in the model and is not included in the CO surface flux.

The apparent increase in tropospheric levels of CH_4 and CO over the past 35 years may have resulted from the following factors: (1) an increase in the global production rate of either, or both CH_4 and CO; (2) a decrease in the global destruction rate of either, or both CH_4 and CO; or (3) a combination of both (1) and (2), since both CH_4 and CO are closely coupled photochemically via the methane oxidation chain and through the hydroxyl radical (OH), the dominant destruction mechanism for both CH_4 and CO in the troposphere.

As mentioned above, the methane oxidation chain, which is initiated by the reaction of CH_4 with OH, and leads to the production of CO via the photolysis of formaldehyde (H_2CO), photochemically couples CH_4 and CO¹⁸⁻²³.

The reaction of CH_4 with OH is the dominant destruction mechanism for CH_4 in the troposphere, and is also a significant loss mechanism for tropospheric OH. The methyl radical (CH_3) formed in reaction (1) continues the methane oxidation chain, which is illustrated in the following reactions:

The methane oxidation chain leads to the photochemical production of CO, H_2 and O_3 , and may be represented by the following net cycle:

Just as the reaction with OH (reaction 1) is the dominant destruction mechanism for CH_4 , the destruction of CO is also controlled by its reaction with OH:

The reactions of OH with CH_4 (reaction 1) and CO (reaction 11) control the global destruction of OH, the dominant oxidizing species in the troposphere, and, hence, the dominant tropospheric scavenging species. The reactions of OH with CH_4 and CO account for about 97% of the total tropospheric destruction of OH (for noontime, groundlevel conditions at 45°N , CO accounts for 81% and CH_4 16% of the total destruction of OH)¹⁰. The reaction between CH_4 and OH is such a dominant loss mechanism for CH_4 that more than 90% of the global destruction of CH_4 occurs in the troposphere, with nearly 80% occurring in the lowest atmospheric scale height¹⁸. Several model studies have considered the photochemical coupling of CH_4 , CO, and OH and the effects of anthropogenic emissions of CO on the CH_4 —CO—OH chemical system²⁴⁻²⁶.

Photochemical calculations can determine the surface flux of CH_4 (or CO) required to maintain a particular tropospheric mixing ratio of CH_4 (or CO). The critical parameter in these calculations is the vertical distribution of OH throughout the troposphere. Our photochemical calculations indicate that at 45°N (neglecting advection), the measured mixing ratio of CH_4 (1.65 p.p.m.v.) is maintained by a surface flux of $1.5 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$ ($645 \text{ Mt}(\text{CH}_4) \text{ yr}^{-1}$) and that a CO surface flux of $6 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$ ($4,200 \text{ Mt}(\text{CO}) \text{ yr}^{-1}$) results in a surface mixing ratio of about 180 parts per 10^9 by volume (p.p.b.v.) decreasing to about 130 p.p.b.v. at 5 km. For this calculation, the OH concentration was found to decrease from $2.9 \times 10^6 \text{ cm}^{-3}$ at the surface to $2.0 \times 10^6 \text{ cm}^{-3}$ at 1 km and then range between 1.0 and $1.5 \times 10^6 \text{ cm}^{-3}$ between 2 and 10 km. The total OH column in the troposphere was $1.6 \times 10^{12} \text{ cm}^{-2}$. The calculation of the OH profile in the troposphere depends on several parameters, including the level of incident solar radiation, which photodissociates tropospheric ozone producing excited oxygen atoms, which then react with water vapor producing OH. The level of incident radiation available for the photodissociation of ozone is a function of season (solar declination), latitude, time of day, and the scattering properties of the atmosphere, including the surface albedo¹². Time-dependent calculations indicate that at the surface at 45°N , the noontime OH concentrations are about $2 \times 10^6 \text{ cm}^{-3}$ for a surface albedo of 10%¹⁰. Photochemical calculations indicate that the concentration of OH increases as the surface albedo is increased¹². For the calculations in this work we have assumed summer conditions (solar declination of 22.5°N) at 45°N with a surface albedo of 25%. These parameters tend to maximize the calculated values of OH. Our calculated OH values are consistent with time-dependent calculations¹⁰ and with calculations with a varying surface albedo¹².

We also investigated the sensitivity of the CH_4 —CO—OH system to changes in the prescribed surface fluxes of CO and CH_4 . We varied the surface CO flux from 4 to $8 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$ (at 45°N , the CO mixing ratio is maintained by a surface CO flux of $6 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$ and a surface CH_4 flux of $1.5 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$). In all of these calculations, we used a surface CH_4 flux of $1.5 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$. The surface concentrations of CO, CH_4 , and OH as a function of the surface CO flux are summarized in Table 1. These calculations

Table 1 Sensitivity of CO, CH_4 and OH to the CO surface flux

CO surface flux (molecules $\text{cm}^{-2} \text{ s}^{-1}$)	Surface mixing ratio		Surface density OH (cm^{-3})
	CO (p.p.b.v.)	CH_4 (p.p.b.v.)	
4×10^{11}	107.0	1.321	3.46×10^6
5×10^{11}	141.1	1.479	3.14×10^6
6×10^{11} *	180.9	1.654	2.85×10^6
7×10^{11}	226.3	1.840	2.60×10^6
8×10^{11}	276.6	2.027	2.38×10^6

For all of these calculations, a CH_4 surface flux of $1.5 \times 10^{11} \text{ molecules cm}^{-2} \text{ s}^{-1}$ was used.

* Standard present-day run.

Table 2 Sensitivity of CH₄, CO and OH to the CH₄ surface flux

CH ₄ surface flux (molecules cm ⁻² s ⁻¹)	Surface mixing ratio		
	CH ₄ (p.p.m.v.)	CO (p.p.b.v.)	Surface density OH (cm ⁻³)
1.0 × 10 ¹¹	0.984	155.0	3.14 × 10 ⁶
1.5 × 10 ¹¹ *	1.654	180.9	2.85 × 10 ⁶
2.0 × 10 ¹¹	2.398	205.6	2.64 × 10 ⁶

For all of these calculations, a CO surface flux of 6×10^{11} molecules cm⁻² s⁻¹ was used.

* Standard present-day run.

tions indicate that if the CO surface flux is doubled (from 4 to 8×10^{11} molecules cm⁻² s⁻¹), the surface CO mixing ratio increased by a factor of 2.6, the surface CH₄ mixing ratio increased by a factor of 1.5 and the OH number density decreased to 69% of its original value. For comparison, in an earlier study²⁴, it was found that by doubling the CO surface flux (from 5 to 10×10^{11} molecules cm⁻² s⁻¹), the surface CO mixing ratio increased by a factor of 2.7, the surface CH₄ mixing ratio increased by a factor of 1.6, and the surface OH number density decreased to 62% of its original value. Similar results were also found in this study for a doubling of the CO surface flux from 1 to 2×10^{10} molecules cm⁻² s⁻¹ (ref. 24).

We also varied the surface CH₄ flux from 1.0 to 2.0×10^{11} molecules cm⁻² s⁻¹ while holding the surface CO flux constant at 6×10^{11} molecules cm⁻² s⁻¹. The surface concentrations of CH₄, CO, and OH as a function of the surface CH₄ flux are summarized in Table 2. These calculations indicate that a doubling of the surface CH₄ (from 1 to 2×10^{11} molecules cm⁻² s⁻¹) results in an increase in the surface CH₄ mixing ratio of a factor of 2.4, an increase in the surface CO mixing ratio of a factor of 1.3, and a decrease in the surface OH number density to 84% of its original value.

Decreased levels of CH₄ and CO in the 1950–51 troposphere may be attributable to a decreased surface flux of CH₄ and/or CO, due to the chemical coupling via the methane oxidation chain and OH destruction. In our calculations, we have assumed that surface fluxes of both CH₄ and CO have increased as a result of anthropogenic perturbations to the production of both gases. Calculations were performed to determine the fluxes of both CH₄ and CO consistent with the lowered CH₄ and CO mixing ratios deduced from the 1950 and 1951 groundbased solar infrared spectra, that is, CH₄ = 1.14 p.p.m.v. and CO about 65 p.p.b.v. in the free troposphere (5 km), which is within the uncertainty in the spectral determination (76 ± 25 p.p.b.v.)². Our results indicate that a CH₄ mixing ratio of 1.14 p.p.m.v. is maintained by a flux of 1.35×10^{11} cm⁻² s⁻¹ ($580 \text{ Mt}(\text{CH}_4) \text{ yr}^{-1}$) and the CO mixing ratio is maintained by a flux of 4.0×10^{11} cm⁻² s⁻¹ ($2,800 \text{ Mt}(\text{CO}) \text{ yr}^{-1}$). These calculations indicate that while the CH₄ mixing ratio increased about 44% from 1951 to the present (1.14 p.p.m.v. to 1.65 p.p.m.v.), the 45° N CH₄ flux increased by only 11% (1.35 to 1.50×10^{11} molecules cm⁻² s⁻¹). During this same period, the CO free tropospheric (5 km) mixing ratio increased by about 100% (from about 65 to about 130 p.p.b.v.), while the 45° N CO flux only increased by 50% (4.0 to 6.0×10^{11} molecules cm⁻² s⁻¹). For this calculation, the OH concentration was found to decrease from 3.6×10^6 cm⁻³ at the surface to 2.6×10^6 cm⁻³ at 1 km and then range between 1.3 and 1.9×10^6 cm⁻³ between 2 and 10 km. The total OH column in the troposphere was 2.1×10^{12} cm⁻³.

Photochemical calculations indicate at 45° N, the OH column in the troposphere decreased by about 25% (from 2.1×10^{12} to 1.6×10^{12} cm⁻²) from 1950 to the present, as a result of increased levels of CH₄ and CO in the troposphere. It is interesting to note that in a recent paper, a decrease in tropospheric OH of between 20 and 30% over the last 130 years was estimated as a result of increasing levels of CH₄²⁷. What is particularly interesting is that this estimate was based on two entirely different methods of analysis (on a mass balance of CH₄ in the

Table 3 Sensitivity of calculated CH₄, CO and OH to reduced NO_x and O₃ in 1950–51 troposphere

O ₃ Reduction	Reduced O ₃ (fixed NO _x)		Surface OH
	Surface CH ₄	CO at 5 km	
–10%	+6%	+8%	–8%
–25%	+17%	+20%	–19%
–50%	+40%	+47%	–38%

NO _x Reduction	Reduced NO _x (fixed O ₃)		Surface OH
	Surface CH ₄	CO at 5 km	
–10%	+2%	+2%	–1%
–25%	+5%	+5%	–6%
–50%	+13%	+13%	–17%

Values are calculated percentage change from standard 1950–51 calculation. In a standard run, the surface O₃ mixing ratio is 29.5 p.p.b.v. and the surface NO_x mixing ratio is 0.5 p.p.b.v.

past and present atmosphere and on calculations of the lifetimes of CH₄ in the past and present atmosphere), neither of which involve photochemical calculations, as does the present analysis. Hence, increasing levels of CH₄ and CO clearly impacted the scavenging ability of OH, the major chemical scavenger in the troposphere.

The calculated concentrations of CH₄, CO and OH are sensitive to the tropospheric levels of the nitrogen oxides, NO_x (NO + NO₂) and ozone (O₃)^{10,11}. Unfortunately, the 1950–51 spectra used to deduce levels of CH₄ and CO can provide no information on tropospheric NO_x and O₃. In fact, there does not appear to be any data base to provide this information. However, we can perform photochemical calculations to determine the sensitivity of the calculated concentrations of CH₄, CO and OH to changes in NO_x and O₃. It appears that both NO_x and O₃ in the troposphere are impacted by anthropogenic activities^{10,11}, and, hence we would expect lower concentrations in the 1950–51 time period. Therefore, we reduced present-day levels of NO_x by 10%, 25% and 50%, while keeping O₃ at the present-day level and then reduced present-day levels of O₃ by 10%, 25% and 50%, while keeping NO_x at the present-day level. The sensitivity of calculated levels of CH₄ and CO on other tropospheric species is summarized in reactions (1) to (11). The concentration of tropospheric OH is given by the following expression, with the OH production terms in the numerator, and the OH destruction terms in the denominator¹⁰:

$$(12) [\text{OH}] =$$

$$\frac{2k[\text{O}(^1\text{D})][\text{H}_2\text{O}] + [\text{HO}_2]\{k[\text{O}_3] + k[\text{NO}]\} + 2J[\text{H}_2\text{O}_2]}{k[\text{CO}] + k[\text{CH}_4]}$$

In this equation, k is the kinetic chemical reaction rate and J is the photolysis rate of H₂O₂. In the lower tropical troposphere, the production of OH occurs mainly by the first term in the numerator, with smaller contributions from the other three terms. Contributions from O₃ and NO grow in importance with latitude reflecting an increase in O₃ and NO due to anthropogenic activities. The photolysis of O₃ leads to the production of excited oxygen atoms (O¹D), which react with water vapour forming OH. Hence, OH production increases with increasing levels of O¹D and H₂O, as indicated by the first OH production term in the numerator. The concentration of OH is independent of NO for NO levels below about 10 parts per 10¹² by volume (p.p.t.v.); OH increases as a function of NO between 10 and 500 p.p.t.v.; and decreases as NO increases above about 1 p.p.b.v.¹⁰ The production of OH via the photolysis of hydrogen peroxide (H₂O₂), represented by the fourth term in the numerator, is a significant source of OH in the upper troposphere¹⁰. Also note that the loss of OH is controlled by its reactions with CH₄ and CO, as shown in the denominator. The results of these sensitivity calculations for reduced tropospheric levels of O₃ and NO_x are summarized in Table 3. Inspection of this table indicates that surface OH concentrations decrease with reduced levels of O₃ and NO_x, as predicted by equation

(12). For all of the reduced levels of O_3 and NO_x , except for the 50% O_3 reduction case, the decrease in OH is less than 20% of the standard 1950 calculation, indicating that OH levels may have indeed decreased from 1950 to the present day, as CH_4 and CO levels increased. The variation of OH as a function of NO_x level summarized in Table 3 is in good agreement with earlier sensitivity calculations^{10,24}.

Photochemical calculations of present-day levels of CH_4 and CO compared to levels of these gases deduced from 1950 and 1951 ground-based solar infrared spectra^{1,2} suggest that at 45° N: (1) the lower surface flux of CH_4 may have increased by about 11% from 1951 to the present, although the CH_4 mixing ratio increased by about 44%; (2) the lower surface flux of CO may

have increased by about 50% from 1950–51 to the present, although the free tropospheric (~5 km) CO mixing ratio increased by about 100%; and (3) increased tropospheric levels of CH_4 and CO from 1950–51 to the present resulted in about a 25% decrease in the tropospheric column of OH, and, hence, impacted the ability of the major tropospheric chemical scavenger to scavenge. Finally, the analysis presented here suggests that historic spectra coupled with photochemical calculations may provide important and previously unattainable information on global production of atmospheric gases over time periods of decades. This information may permit an assessment of the role of anthropogenic emissions to the global budgets of atmospheric species over these time periods.

Transposition of structural genes to an expression sequence on a linear plasmid causes antigenic variation in the bacterium *Borrelia hermsii*

Ronald H. A. Plasterk*, Melvin I. Simon* & Alan G. Barbour†

* California Institute of Technology, Division of Biology 147–75, Pasadena, California 91125, USA

In Borrelia hermsii, a spirochaete that causes relapsing fever, the switch between expression of two frequent variable major protein (VMP) types (7 and 21) is associated with a DNA rearrangement. Both cell types 7 and 21 contain untranscribed 7 and 21 VMP genes on linear plasmids. The serotype 7 cells contain an additional copy of the 7 VMP gene fused to an expression sequence on another linear plasmid. Switching to the 21 serotype involves removal of the transcribed 7 VMP gene and fusion of a copy of the 21 VMP gene to this same expression sequence. Thus recombination between linear plasmids can activate different VMP genes.

PATHOGENIC microorganisms have strategies to escape the host's antibody response. The selective pressure to develop evasive mechanisms is especially strong for extracellular pathogens that cycle between the vertebrate bloodstream and haematophagous arthropods: the longer the parasite survives in the bloodstream, the greater the probability of transmission through an arthropod to another animal. One of the strategies that these pathogens have developed is antigenic variation: a small fraction of multiplying cells undergoes a genetic change leading to the synthesis of a new and antigenically distinct surface protein. Those cells possessing novel serotypic determinants escape the immune response that is directed against the infecting serotype. The consequence to the host of antigenic variation is a relapsing or chronic illness.

Multiphasic antigenic variation has been described in eukaryotic and prokaryotic organisms. Salivarian trypanosomes such

as *Trypanosoma brucei* have a large assortment of surface glycoprotein genes that can be expressed in the host¹. Surface proteins of the bacterium *Neisseria gonorrhoeae* can vary during infection of human mucosa². Another group of bacteria, the borreliae, change their surface antigens during the course of relapsing fever and, like trypanosomes, are blood-borne and transmitted by vector³.

We are studying the molecular basis for antigenic variation in a *Borrelia* sp. for several reasons. (1) The antigenic repertoire is elaborate: 26 variant serotypes have derived from one serotype^{4,5}. (2) Infection in mice can be started with a single *Borrelia*⁴. (3) The organism can be cultivated *in vitro*⁶. (4) The variable antigens are abundant surface proteins that differ extensively in their primary structures^{7–9}. (5) Antigenic variation has been observed *in vivo* and *in vitro* at a frequency of 10^{-4} (ref. 4). These properties allow the isolation of populations of clonal origin, development of specific antibody and nucleic acid probes, and analysis of genetic material before and after the antigenic switch.

Recently, it was demonstrated that switching between three

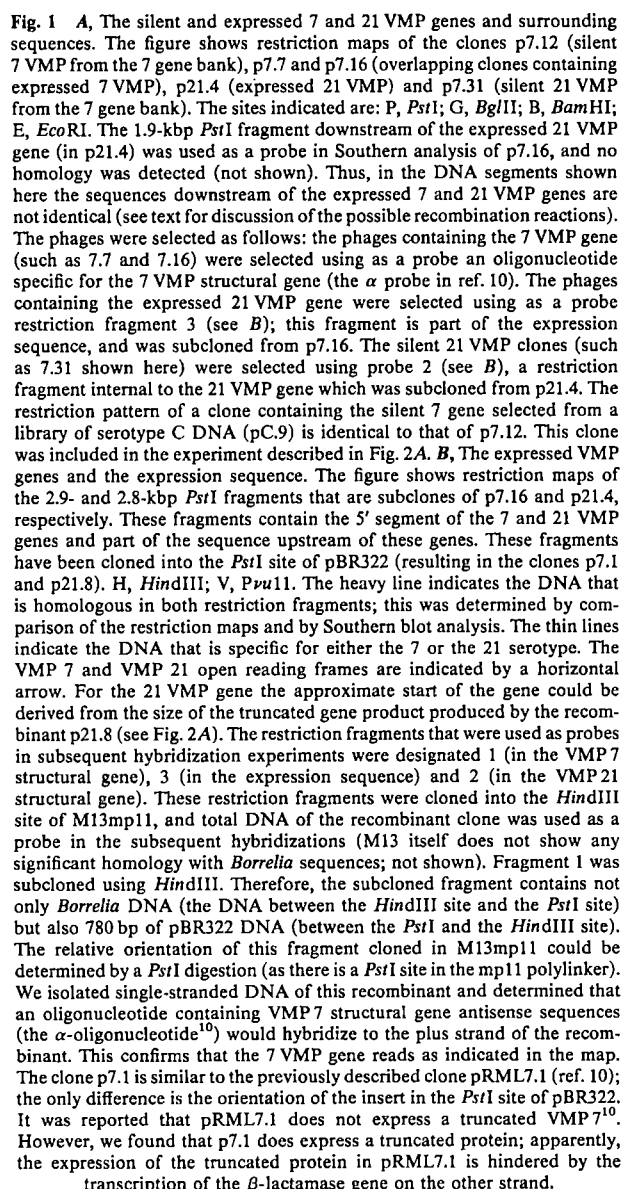

Fig. 1 A. The silent and expressed 7 and 21 VMP genes and surrounding sequences. The figure shows restriction maps of the clones p7.12 (silent 7 VMP from the 7 gene bank), p7.7 and p7.16 (overlapping clones containing expressed 7 VMP), p21.4 (expressed 21 VMP) and p7.31 (silent 21 VMP from the 7 gene bank). The sites indicated are: P, *Pst*I; G, *Bgl*II; B, *Bam*HI; E, *Eco*RI. The 1.9-kbp *Pst*I fragment downstream of the expressed 21 VMP gene (in p21.4) was used as a probe in Southern analysis of p7.16, and no homology was detected (not shown). Thus, in the DNA segments shown here the sequences downstream of the expressed 7 and 21 VMP genes are not identical (see text for discussion of the possible recombination reactions). The phages were selected as follows: the phages containing the 7 VMP gene (such as 7.7 and 7.16) were selected using as a probe an oligonucleotide specific for the 7 VMP structural gene (the α probe in ref. 10). The phages containing the expressed 21 VMP gene were selected using as a probe restriction fragment 3 (see B); this fragment is part of the expression sequence, and was subcloned from p7.16. The silent 21 VMP clones (such as 7.31 shown here) were selected using probe 2 (see B), a restriction fragment internal to the 21 VMP gene which was subcloned from p21.4. The restriction pattern of a clone containing the silent 7 gene selected from a library of serotype C DNA (pC.9) is identical to that of p7.12. This clone was included in the experiment described in Fig. 2A. B, The expressed VMP genes and the expression sequence. The figure shows restriction maps of the 2.9- and 2.8-kbp *Pst*I fragments that are subclones of p7.16 and p21.4, respectively. These fragments contain the 5' segment of the 7 and 21 VMP genes and part of the sequence upstream of these genes. These fragments have been cloned into the *Pst*I site of pBR322 (resulting in the clones p7.1 and p21.8). H, *Hind*III; V, *Pvu*II. The heavy line indicates the DNA that is homologous in both restriction fragments; this was determined by comparison of the restriction maps and by Southern blot analysis. The thin lines indicate the DNA that is specific for either the 7 or the 21 serotype. The VMP 7 and VMP 21 open reading frames are indicated by a horizontal arrow. For the 21 VMP gene the approximate start of the gene could be derived from the size of the truncated gene product produced by the recombinant p21.8 (see Fig. 2A). The restriction fragments that were used as probes in subsequent hybridization experiments were designated 1 (in the VMP 7 structural gene), 3 (in the expression sequence) and 2 (in the VMP 21 structural gene). These restriction fragments were cloned into the *Hind*III site of M13mp11, and total DNA of the recombinant clone was used as a probe in the subsequent hybridizations (M13 itself does not show any significant homology with *Borrelia* sequences; not shown). Fragment 1 was subcloned using *Hind*III. Therefore, the subcloned fragment contains not only *Borrelia* DNA (the DNA between the *Hind*III site and the *Pst*I site) but also 780 bp of pBR322 DNA (between the *Pst*I and the *Hind*III site). The relative orientation of this fragment cloned in M13mp11 could be determined by a *Pst*I digestion (as there is a *Pst*I site in the mp11 polylinker). We isolated single-stranded DNA of this recombinant and determined that an oligonucleotide containing VMP 7 structural gene antisense sequences (the α -oligonucleotide¹⁰) would hybridize to the plus strand of the recombinant. This confirms that the 7 VMP gene reads as indicated in the map. The clone p7.1 is similar to the previously described clone pRML7.1 (ref. 10); the only difference is the orientation of the insert in the *Pst*I site of pBR322. It was reported that pRML7.1 does not express a truncated VMP7¹⁰. However, we found that p7.1 does express a truncated protein; apparently, the expression of the truncated protein in pRML7.1 is hindered by the transcription of the β -lactamase gene on the other strand.

Similar conclusions were drawn from Western blot analysis of *E. coli* strains containing p7.1 or p21.8. Figure 2A shows that

Fig. 2 A, Western blot analysis of lysates of *B. hermsii* or of *E. coli* containing recombinant plasmids, with *Borrelia* DNA. Monoclonal antibody H12436 (9) is anti-VMP 7 ($\alpha 7$; left-hand panel); monoclonal antibody H10022 (9) is anti-VMP 21 ($\alpha 21$; right-hand panel). Lanes contained lysates of *B. hermsii* serotypes 7 (B.h.7) or 21 (B.h.21) or lysates of *E. coli* JM101 containing p7.16, p7.12, pC.9, p21.4 or p21.8. On the left are shown the relative migrations of pre-stained M_r standards (6041SA; BRL). *B. hermsii* cells were cultured, collected and lysed as described previously^{9,10}. The *E. coli* were grown in CYHM medium (1% Difco casamino acid, 0.5% Difco Bacto yeast extract, 50 mM NaCl, 25 mM KCl, 10 mM MgCl₂ and 20 mM HEPES pH 7.4). Harvested cells were resuspended in phosphate-buffered saline containing 5 mM MgCl₂ and 20 $\mu\text{g ml}^{-1}$ of phenylmethylsulphonyl fluoride and incubated for 15 min at 25 °C, then centrifuged. The pellet was resuspended in sample buffer containing 1% SDS and boiled for 5 min. The lysate was cleared by centrifugation; lysate components were analysed by Western blot analysis as described previously⁹. The blocking and antibody incubation solution comprised 2% bovine serum albumin in 50 mM Tris-HCl pH 7.6, 150 mM NaCl, 5 mM EDTA (TSE); the washing and ¹²⁵I-protein A incubation solution comprised 0.05% Tween 20 in TSE. **B**, Northern blot analysis of RNA from the three serotypes 7, 21 and C. The left-hand panel shows analysis of the three types of RNA using probe 1 (from the 7 VMP gene); this probe hybridizes to one major band that is present only in the 7 strain. Similarly, the probe from the 21 gene (2) hybridizes to a band of approximately the same size (1,100 bases) that is present only in the 21 strain. This result shows that the difference between the two strains in VMP expression is indeed at the transcriptional level, and that the probes used are indeed specific for the different VMP genes.

Methods. The experiments were done as follows: total *Borrelia* RNA was isolated and electrophoresed as described¹⁰, transferred to a Biohyne Nylon membrane and baked under vacuum. After 1 h of prehybridization, the blot was incubated at 37 °C for 16 h in 6 \times SSC, 50% formamide, 1% SDS, 0.1 \times Denhardt's and 100 $\mu\text{g ml}^{-1}$ sonicated *E. coli* DNA and the probe. Probes were made by nick-translation of the subclone DNA, using 40 μCi of [α -³²P]dATP per reaction. Free nucleotides were removed by spinning the sample through a 200- μl BioRad P200 column. After hybridization the blots were rinsed at room temperature and washed in 2 \times SSC, 1% SDS at 50 °C for 30 min. Exposure was for between 2 and 16 h at -70 °C with an intensifying screen.

recombinant p21.8 expresses a truncated VMP 21. Similarly, the recombinant p7.1 expresses a truncated VMP 7 (not shown). Thus, the *Pst*I site interrupts the coding sequence of both VMP genes. This result also indicates the direction of reading of the VMP genes, as the 5' end of the gene is apparently contained within the subcloned fragment.

Activation of VMP genes

The RNA analysis showed that the switch from serotype 7 to serotype 21 involves switching-off VMP 7 transcription and switching-on VMP 21 transcription. We showed that expression of the VMP genes in *E. coli* is associated with juxtaposition to a specific DNA segment. If the exclusive expression of one VMP gene is the result of the presence of that VMP gene adjacent to the expression sequence, then the switch from serotype 7 to 21 should involve the replacement of the 7 VMP gene adjacent to the expression sequence by the 21 VMP gene. The probes specific for the 7 or 21 VMP genes (1 and 2) were used to follow the fate of the 7 and 21 VMP genes in the switch.

Figure 3A, panel b shows *Pst*I-digested DNA from 7, 21 and C cells, hybridized with probe 1. All three strains contain a fragment of 8.5 kbp that hybridizes with the probe. The same fragment is found in clone p7.12, which does not express VMP 7; this suggests that the 8.5-kbp fragment represents the silent form of the 7 VMP gene in all serotypes. The 7 DNA contains an additional fragment of 2.9 kbp that hybridizes with the probe; this is the fragment found in clone p7.16 (the VMP 7-expressing clone). The expressed copy of the 7 VMP gene is no longer present after the switch to the 21 serotype. When the VMP 21-specific probe (2) was used, a 1,250-base pair (bp) *Pst*I fragment was observed in the three serotypes (Fig. 3A, panel c); this is the fragment present in clone p7.31 which contains the silent 21 VMP gene. In addition to this fragment, the 21 DNA contains a 2.8-kbp fragment that hybridizes with the probe, and this is

the fragment that is found in the VMP 21-expressing clone in which the 21 VMP gene is fused to the expression site. This result shows that the activation of the 21 VMP gene is also associated with a duplication of the gene and fusion to the expression sequence.

The above results suggest that in each serotype the expression sequence is fused to a different VMP gene. To demonstrate this, we used the expression sequence (fragment 3, Fig. 1B) as a probe in a Southern blot analysis; the fragments specific for the expressed 7 VMP gene and the expressed 21 VMP gene showed hybridization (2.9 and 2.8 kbp respectively; see Fig. 3A, panel a). In the C serotype the expression sequence is fused to yet another DNA segment (resulting in a 3.9-kbp *Pst*I segment). In addition, probe 3 hybridized to a 4.7-kbp fragment common to all serotypes (see legend to Fig. 3A).

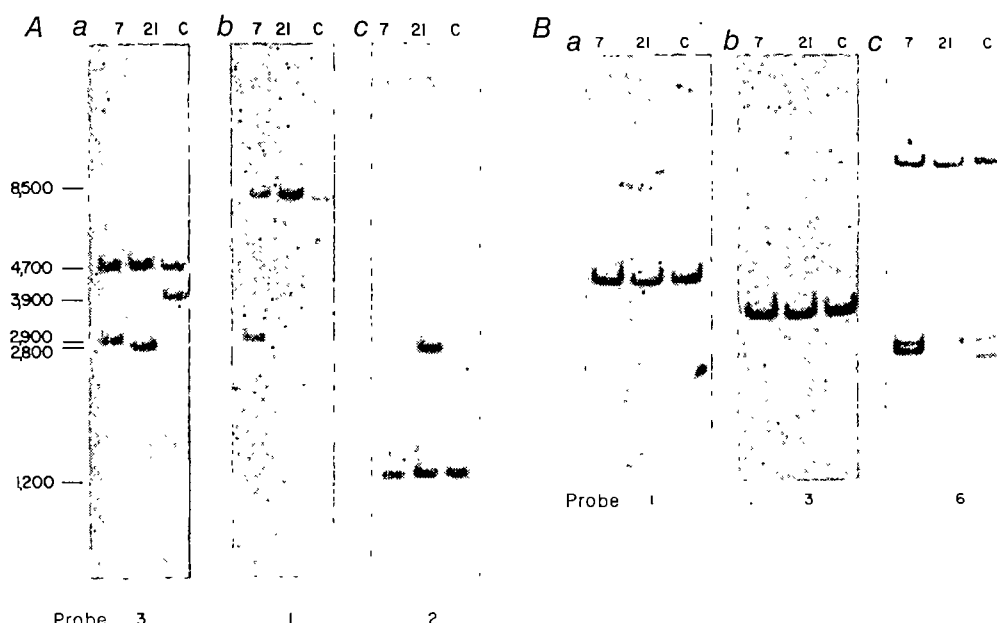

Several conclusions can be drawn from these data: in the 7 serotypes two copies of the entire 7 VMP gene are found. One of these copies is the transcribed copy, and this is fused to the expression sequence. In addition, the cells contain an untranscribed copy of the 21 VMP gene. When the cells switch to serotype 21, the copy of the 7 VMP gene that is adjacent to the expression site is replaced by a copy of the 21 VMP gene.

The site at which the expression sequence and the VMP gene are fused can be referred to as the recombination site. In the expressed VMP clone this site was mapped as follows: the 2.9-kbp *Pst*I fragment containing the site was divided into *Hind*III fragments. Each of these fragments was used as a probe of *Hind*III-digested DNA from different serotypes. The *Hind*III fragment containing the recombination site should show a pattern that is different in the three strains. As shown in Fig. 3B, the fragment numbered 6 contains the recombination site. No other rearrangement was seen in this 2.9-kbp *Pst*I fragment.

We have shown that the activation of a VMP gene is the result of fusion of that gene to the expression site. We do not know

Fig. 3 **A**, Southern analysis of *Pst*I-digested DNA from the three serotypes 7, 21 and C. The probes were 3(a), 1(b) and 2(c). Probe 1 hybridizes to an additional band of 2.9 kbp in the 7 DNA; probe 2 hybridizes to an additional 2.8-kbp fragment in the 21 DNA. Note that probe 3 hybridizes to a 2.9-kbp fragment in the 7 DNA and also a 2.8-kbp band in the 21 DNA, as well as to a 3.9-kbp fragment in the C DNA. All three of these fragments are specific for each serotype. In addition, probe 3 hybridizes to a fragment of 4.7 kbp that is present in all three serotypes; this *Pst*I fragment has been mapped. The plasmids p7.7 and p21.4 (that is, the plasmids containing the expression site) contain a 4.7-kbp *Pst*I fragment that hybridizes with probe 3 (not shown). This *Pst*I fragment was mapped adjacent to the *Pst*I fragment that contains the recombination site (see Fig. 1a). Nick-translation and hybridization

were done as described in Fig. 2 legend, except that hybridization was done at 42 °C, and the final washing was at 65 °C in 0.1×SSC, 1% SDS. The film was exposed for 2 h at -70 °C. **B**, Southern blot analysis of *Borrelia* DNA of three serotypes (7, 21 and C) digested with *Hind*III. **a**, The hybridization pattern obtained when subclone 1 was used as a probe (see Fig. 1). **b**, Same blot as **a** after removal of the first probe and hybridization with probe 3. **c**, Same blot again, but after hybridization with probe 6. The pattern using probes 1 and 3 is identical in all three lanes; that using probe 6 is different in each lane.

how the expression site activates the adjacent VMP gene; one possible explanation is that it contains a promoter for transcription reading into the adjacent DNA.

VMP genes carried on linear plasmids

We obtained an unusually high frequency of positive clones (5–10%) in the 7 and 21 phage banks, using probes that on Southern analysis of digested total DNA hybridized to only one or a few restriction fragments. If these genes were represented only once per genome this would predict an unusually small genome size. The most likely explanations are either that the genes are present in multiple copies in the chromosome of *B. hermsii* or that they are present on plasmids with a high copy number per cell. To resolve this issue we ran the total DNA on 0.5% agarose gels and observed several discrete bands. A better and quicker separation was achieved by pulse-field electrophoresis¹². The resolved bands were relatively small (~30 kbp) and optimal separation was obtained using short pulse times (1 s). Figure 4A shows total DNA from three *Borrelia* serotypes separated by pulse-field gel electrophoresis. The top band is the *Borrelia* chromosome (as a reference we included DNA from *E. coli* that was isolated using the same lysis and purification procedure; it co-migrated with the *Borrelia* chromosome). The banding patterns for serotypes 7 and 21 are very similar. Note, however, that the structure of the DNA of the C serotype is different—an extra band is visible. The fact that these molecules can be separated by pulse-field electrophoresis suggests that they are linear DNA molecules, as this technique does not resolve circular DNA well¹² (see below). The presence of extrachromosomal DNA does not seem to be unique to *B. hermsii*: as shown in Fig. 4A, the species *Borrelia burgdorferi*, the cause of Lyme disease, contains numerous bands. *E. coli* K-12 (Fig. 4A) and *Spirochaeta aurantia*, a free-living non-pathogenic spirochaete (not shown), yielded no detectable extrachromosomal DNA in this experiment. The simplest explanation for these bands is that they represent discrete extrachromosomal elements, that is, plasmids.

To determine whether these DNA elements contain the silent and expressed VMP genes, we probed the DNA separated by electrophoresis on a 0.7% agarose gel with probes for the 7 and

21 VMP genes and the expression site. As shown in Fig. 4B, the expression site lies on an extrachromosomal element of ~28 kbp in both the 7 and 21 strains. The VMP 7-specific probe hybridized to the 32-kbp plasmid in the 21 strain. Thus, the silent 7 VMP gene lies on a plasmid other than the one carrying the expression site. In the 7 strain two plasmids hybridized with the VMP 7 probe: one (32 kbp) containing the silent 7 VMP gene and the other (28 kbp) containing the expressed 7 VMP gene. In the 7 DNA the 28-kbp band hybridized with the VMP 2-specific probe. This result means that the silent 21 VMP gene is carried on a plasmid of the same size as the plasmid that carries the expression site. A clone of approximately 15 kbp containing the silent 21 gene (p7.31) contains no homology with clones of the expressed 7 gene (p7.7 and p7.16), which indicates that the silent 21 gene lies on a DNA molecule of 28 kbp that is different from the expression plasmid. This pattern shows that in the switch from type 7 to 21, the 7 VMP gene is removed from the 28-kbp plasmid, and a copy of the 21 VMP gene is inserted into the same site on the 28-kbp plasmid.

The behaviour of the extrachromosomal elements in pulse-field electrophoresis suggested that they might be linear rather than circular DNA molecules. We wanted to test whether the DNA of 28 kbp was indeed linear, and if so, whether the sequences on the molecule were circularly permuted. Therefore, we treated the putative ends of the DNA molecule with an exonuclease. If the DNA is linear and has specific ends, treatment with an exonuclease followed by restriction enzyme digestion and gel electrophoresis should result in a shift in the relative molecular mass (M_r) of specific restriction fragments. As we could obtain only small amounts of the 28-kbp DNA, we did the experiment as follows: total DNA from the 7 serotype was digested for different lengths of time with *Bal*31 nuclease. The DNA was then digested with *Pst*I and separated on a gel. The fragments contained in the 28-kbp band were visualized by Southern blotting and hybridization with nick-translated 28-kbp plasmid DNA. The result is shown in Fig. 5A: the probe hybridized to a series of *Pst*I fragments in the 7 DNA, but only one of these bands showed a shift down of M_r after treatment with *Bal*31 nuclease. Once this band had been degraded, a second band began to shift down. We concluded from this experiment

Fig. 4 **A**, Pulse-field gel electrophoresis of *Borrelia* DNA. DNA from *B. hermsii* and *E. coli* was isolated as described¹⁰ and separated as follows: a 1.1% agarose gel was placed in a tray with two pairs of electrodes (a slight modification of the original method described by Schwartz and Cantor¹², Stanford workshop); 10 μ l of DNA was loaded per lane and electrophoresis was at 175 V for 16 h, with the field changing every second. The gel was stained with ethidium bromide and photographed as any DNA/agarose gel. The top band is the chromosomal DNA (in lane 5, *E. coli* chromosomal DNA is shown). In addition, there are several extrachromosomal DNA elements visible. The pulse time (1 s) was chosen to optimize separation of the 28-kbp band from the 32-kbp band. When longer times are chosen the larger elements are separated better, and it is then clear that the band just beneath the chromosomal band is indeed separate. **B**, Southern analysis of the extrachromosomal *Borrelia* DNA. Total *Borrelia* DNA from the 7 and 21 serotypes was separated on a 0.7% agarose gel (25 V, 60 h at 4 °C). The resulting pattern is identical to that shown in **A**. We chose standard separation in a low-percentage gel rather than in a high-percentage gel in pulse-field electrophoresis because the capillary transfer of large molecules is better from a low-percentage gel. However, the experiment has also been done after transfer from a pulse-field gel, or by hybridizing to the dried gel itself, with similar results. The gel was treated briefly with 0.25 M HCl, then the DNA was transferred as described above and hybridized with the probes as indicated. The same blot was used with all three probes.

that the 28-kbp band results from a linear DNA molecule having specific ends. We do not yet know in what form this molecule exists in the cell. It seems probable, however, that the ends of the DNA molecule are held together by other macromolecules in the cell (for example, proteins). As only one restriction fragment shifted in the gel in Fig. 5A, it seems that one of the ends of the plasmid was protected from degradation, for example by an amino acid or peptide that was covalently bound and was not removed by the protease and phenol treatment during the DNA purification. We have used nick-translated restriction fragments instead of the total 28-kbp DNA as probes for similar gels. Using the expression-linked 21 VMP gene as a probe (probe 2) with *Bal31* digestion of serotype 21 DNA, it was shown that this fragment is degraded late in the time series (see Fig. 5B),

Fig. 5 *Bal31* degradation of the terminal region of the 28-kbp plasmid. **A**, *Borrelia* DNA (serotype 7) was treated for the indicated time with 0.15 units of *Bal31* (Boehringer Mannheim). EDTA was added to a final concentration of 20 mM, then the DNA was recovered by alcohol precipitation and digested with *Pst*I before separation on a 1% agarose gel. After blotting the gel was hybridized with '28-kbp probe'. This probe was obtained as follows: serotype 7 DNA was run out on a pulse-field gel, and after ethidium bromide staining the 28-kbp plasmid band was cut out of the gel, and the DNA recovered from it. Then it was nick-translated as described above. The arrow labelled I indicates the first band that disappears; the arrow labelled II indicates the second band. **B**, 21 DNA was treated in a time series with *Bal31* as described for **A**. As a probe we used clone 2 (see Fig. 1B), which is a restriction fragment internal to the 21 VMP gene. The two bands that are seen are the 1,250- and 2,800-bp fragments observed in Fig. 3A, corresponding to the silent and the expressed 21 gene respectively. The fragments were initially not affected during the time series. The timepoints are shown at which suddenly both bands began to shift down simultaneously.

hence the transcribed 21 VMP gene is located several kilobases away from the nuclease-sensitive end on a linear plasmid. Note that the bands corresponding to the silent and expressed 21 VMP genes shifted down at the same time; they are therefore at approximately the same distance from the *Bal31*-sensitive end of the plasmids, so the distance from the 21 VMP gene to the end of the plasmid downstream of the gene is not significantly changed by the recombination of the silent gene into the expression site.

Switch mechanism

A schematic representation of the molecular basis of antigenic variation is given in Fig. 6. We have shown for two VMP genes that expression results from the presence of a copy of the gene

Fig. 6 Model for the molecular basis of antigenic variation in *Borrelia*. The relevant plasmids of the 7 and 21 serotypes are shown. The storage plasmids are identical in both strains. The 21 VMP gene in the 7 cells is not transcribed. It transposes into the expression site, and the resident 7 VMP gene is removed. The VMP gene that is adjacent to the expression sequence is transcribed. As discussed in the text, several mechanisms for the recombination reaction are possible, but we favour the one in which a reciprocal site-specific recombination is followed by loss of one of the two reaction products.

in the expression site on the 28-kbp plasmid. When the serotype switches from 7 to 21, the copy of the 7 VMP gene in the expression site is removed and replaced by a copy of the 21 VMP gene. The silent copies of the 7 and 21 VMP genes seem unaffected by the switch.

There are three possible mechanisms for the actual recombination reaction: (1) The switch could be the result of a single reciprocal site-specific recombination reaction with subsequent loss of one of the recombination products. (2) The silent genes could lie on 'cassettes' which can be activated by a duplicative transposition. This would then involve a gene conversion event or two cross-overs at either end of the cassette. (3) The silent VMP genes could be activated by insertion of a transposable DNA element upstream of the genes. Model (2) would predict that, in addition to the recombination site that we described, there would be a second recombination site at the other end of the cassette. In model (3) the second site would be at the other end of the inserted transposable element. We have found no such sites. The restriction maps upstream of the expressed 7 and 21 genes are completely colinear for at least 10 kbp, which makes model (3) unlikely. The sequences 3' of the expressed 21 gene (the 2 kbp present in p21.4) show no homology to those 3' of the expressed 7 gene in p7.16, which makes model (2) unlikely. As the plasmids are linear, it is conceivable that the recombination reaction responsible for the switch is a single site-specific cross-over between two linear plasmids. The fact that the approximate distance from the 21 VMP gene to the downstream end of the plasmid is unchanged after the switch is compatible with this idea. On the basis of present evidence, model (1), the single site-specific recombination event, seems the most likely.

The net result of the recombination reaction that fuses a new VMP gene to the expression site will initially be that the cell contains both types of expression plasmids (assuming that only one plasmid switches at a time). For example, in the case described here the plasmid containing the expressed 7 VMP gene could recombine with the plasmid containing the silent 21 gene. The products are the 21 expression plasmid, and another DNA molecule that either segregates out or is actively removed. The cell then contains both type 7 and type 21 expression plasmids. The immune system presumably selects for the segregants that no longer contain the 7 expression plasmid. A prediction following from this model is that cells that express two VMPs at the same time should be detectable *in vitro*. This prediction is now being tested.

Serotype C is different from the serotypes recovered from spirochaetaemic mice. VMP C is much smaller than the VMPs found *in vivo*⁵. No antigenic switching of serotype C cells has

been observed in culture medium, and no relapses have been noted after infection of a mouse with serotype C cells (A.G.B., unpublished observations). As shown, serotype C DNA contains an extra element; it is this DNA segment that contains the expression site for the 7 and 21 VMP genes, and this sequence is fused to yet another sequence in the C strain (Fig. 3A). At present it is unknown whether the sequence is indeed fused to the expressed C VMP gene. The site may be 'empty' and the expressed C gene may be found in another expression site.

We chose to analyse one switch in detail, but it is not necessarily true that the other 24 antigenic types thus far found after infection are all switched on by recombination of the corresponding VMP gene into the same site. A similar analysis to that described here of cell lines of other serotypes will show whether this is the case.

Genetic switches in other organisms

There exist several other examples of DNA rearrangements in prokaryotes that are responsible for switches in gene expression¹³⁻¹⁵. The mechanism of gene activation by recombination of silent genes into an expression site is known in eukaryotes. A binary switch exists in yeast, where the mating type varies by transposition of a silent gene into the *MAT* locus¹⁶. The protozoan *Trypanosoma brucei* can vary its antigens by a mechanism that is very similar to the one described here¹. The parallels between the bacterial and the eukaryotic infectious microorganisms *B. hermsii* and *T. brucei* are striking: the function of the switch (to escape the host immune system), the mechanism of the switch (recombination into an expression site on minichromosomes) and the ordered appearance of the different serotypes are found in both cases^{1,4,5}. It is tempting to speculate on an evolutionary relationship between the two microorganisms. A more likely alternative, however, is that the strong and very direct selective pressure provided by the immune system has resulted in convergence of these two blood-borne and vector-transmitted microorganisms. DNA rearrangements provide the immune system with a means of generating antibodies against a large number of infections; this finds its complement in a system of DNA rearrangements in the microorganism that is designed to escape the immune system.

Linear plasmids and pathogenicity

We have shown that the silent and expressed genes for two surface proteins of *B. hermsii* lie on linear extrachromosomal elements, based on the following evidence. The high frequency with which clones carrying specific VMP genes are found in gene banks shows that these genes must be present many times in the genome. On low-percentage agarose gels and in pulse-field gels, there occur discrete bands of DNA that are not covalently linked to the chromosome. Probes specific for the VMP genes hybridize to these extrachromosomal DNA elements (and not to the chromosome). The DNA molecules carrying the VMP genes have specific ends that are sensitive to degradation by *Bal*31 nuclease.

Linear genetic elements have been found previously in prokaryotic cells, but usually they are only transiently linear (for example, several bacteriophages on infection). The DNA of *Bacillus* phage ϕ 29 exists in linear form in the cell and has proteins attached to its ends¹⁷. Linear DNA has been observed in yeast *Streptomyces* sp.¹⁸ and in the mitochondria of a number of Protozoa¹⁹. In *B. hermsii* we detected no circular DNA that hybridizes with the probes specific for the VMP genes, therefore the linear form is probably the replicating form of the plasmid. (Circular plasmid DNA can be isolated from *Borrelia*, but this DNA did not hybridize with the VMP-specific probes; J. Meier and A.G.B., unpublished.) We have demonstrated that after deproteination the DNA molecules are linear, but we do not yet know how the molecules exist in the cell. The fact that only one of the two ends of the molecule seems sensitive to *Bal*31 nuclease could mean that there is a covalent modification at one end of the molecule.

Linear plasmids have not been observed previously in pathogenic microorganisms. However, the usual techniques for separating extrachromosomal DNA from the chromosome are largely unsuitable for detecting linear plasmids. On CsCl ethidium bromide gradients, linear extrachromosomal DNA cannot necessarily be separated from the chromosomal DNA. Several other methods for isolation of plasmid DNA allow isolation of only relatively small DNA molecules. There are clear advantages for an infectious microorganism in having a battery of silent and expressed surface protein genes on extrachromosomal DNA: the copy number of the expression plasmid can be high (which facilitates high levels of expression), and

rearrangements can occur at high frequency to activate silent genes, without affecting the stability of the chromosome. An extensive search of other pathogenic microorganisms (and especially those that have a large repertoire of variable antigens) using the technique of pulse-field electrophoresis may reveal an important role of linear extrachromosomal DNA in pathogenesis.

This work was supported in part by grant DMB 820,9295 from the NSF to M.I.S. and by a grant of the Dutch Organization for the Advancement of Pure Scientific Research to R.H.A.P. We thank our colleagues Joe Meier and Sven Bergstrom for useful discussions.

A cDNA clone encoding an *S*-locus-specific glycoprotein from *Brassica oleracea*

J. B. Nasrallah*, T.-H. Kao†, M. L. Goldberg‡ & M. E. Nasrallah*

* Sections of Plant Biology, † Biochemistry, Molecular and Cell Biology and ‡ Genetics and Development, Cornell University, Ithaca, New York 14853, USA

The pollen-stigma interaction resulting in self-incompatibility in the cruciferous plant Brassica has been correlated with glycoproteins that display polymorphisms in all S genotypes examined. A complementary DNA clone encoding these glycoproteins has been isolated and characterized. Polymorphisms in homologous restriction fragments of Brassica genomic DNA segregate precisely with alleles at the S locus.

IN many species representing very diverse angiosperm families, self-fertilization is blocked by a mechanism termed self-incompatibility¹. Following self-pollination, interaction between the stigma or style and pollen elicits a defined morphological response preventing normal pollen tube growth; fertilization is prevented because these pollen tubes are unable to penetrate the full length of the stigma and style. The specificity of the incompatible interaction is determined by one or more genetic loci, and requires that the alleles carried by the male and female parents are identical. In the crucifer *Brassica*, the self-incompatible reaction is localized at the stigma surface, and occurs within minutes after the initial contact between the pollen and the papillar cells on the outer surface of the stigma. In this genus, self-incompatibility is under the control of a single genetic locus, the *S* locus, which is highly polymorphic, some 50 alleles having been identified^{2,3}.

A molecular analysis of the genetic control of incompatibility may best be performed by detecting antigens specific to various *S*-locus alleles in stigma homogenates from different *Brassica* strains⁴. These antigens have been shown to correspond to glycoproteins that may be resolved in various electrophoretic systems⁵⁻⁸. Several lines of evidence suggest that these glycoproteins have an important role in incompatibility. (1) The mobilities of these molecules vary in stigma extracts derived from *Brassica* strains with different *S*-locus alleles⁸. (2) These molecules are found in the stigma but not in style or seedling tissue⁹. (3) The increased rate of synthesis of these *S*-locus-specific glycoproteins (SLSGs) in the developing stigma correlates with the onset of the incompatibility reaction in the stigma⁹. (4) Mutations in genes unlinked to the *S* locus which result in self-compatibility are also associated with reduced levels of these

molecules¹⁰. (5) Most importantly, the inheritance of the various forms of SLSG correlates perfectly with the segregation of *S* alleles in genetic crosses, indicating that the gene responsible for this polymorphism must be genetically located at or extremely closely linked to the *S* locus^{6,11}.

Here we report the isolation of a complementary DNA clone containing sequences encoding an *S*-locus-specific glycoprotein from *Brassica oleracea*. We show that the spatial and temporal distribution of the messenger RNA homologous to these sequences mirrors the appearance of the *S*-locus-specific glycoprotein. Several fragments of *B. oleracea* genomic DNA, generated by restriction endonucleases, hybridize with the SLSG cDNA clone; polymorphisms in certain of these fragments segregate precisely with alleles at the *S* locus.

Isolation

Our strategy for isolating SLSG-encoding DNA sequences was based on the finding that, in some *Brassica* strains, ~5% of the protein synthesis in the self-incompatible bud stigma is devoted to the SLSG synthesis⁹. Thus, it seemed likely that a high proportion of clones in a cDNA library constructed with poly(A)⁺ RNA from mature, incompatible stigmas would contain SLSG sequences. It had also been observed previously that SLSG molecules appear in the stigma but not in leaf or seedling tissue⁸. We thus expected that in such a library SLSG cDNA clones would be enriched in the fraction of clones that would hybridize strongly to radioactive cDNA¹² corresponding to mature stigma mRNA, but not to labelled leaf or seedling-specific cDNA. Poly(A)⁺ RNA from incompatible stigmas was therefore isolated and used as a template for a cDNA library constructed in the plasmid pBR322 using *Bam*HI linkers¹³.

Fig. 1 Temporal regulation of pBOS5-specific RNA and of SLGG expression in the S_6S_6 homozygote. *a*, Northern analysis of RNA from *Brassica* tissues. L, leaf tissue; S, stylar tissue; -3, -2, -1, +1 and +2 refer to stigma developmental stages in days before or after anthesis. *b*, Synthesis of SLGG in developing stigmas. The origin of isoelectric focusing 'O' on the autoradiograph and the generated pH gradient are indicated. The arrow indicates the S_6 -specific SLGG band. Lane designations as in *a*.

Methods. Each inflorescence was divided into developmental zones designated -3, -2, -1, +1 and +2, each consisting of a sequence of three flowers or flower buds. Stigmas from the -3, -2 and -1 zones were stigmas derived from immature flower buds that would normally reach anthesis in 3, 2 and 1 days, respectively; stigmas from the +1 and the +2 zones were mature stigmas from flowers at 1 and 2 days past anthesis, respectively. Stigmas from the -3 and -2 zones are self-compatible, while those from the remaining zones are self-incompatible. *a*, RNA was isolated from *Brassica* tissues using an SDS-proteinase K extraction procedure^{21,22}. Samples containing 1 μ g of denatured RNA were electrophoresed on 1% (w/v) agarose gels in the presence of formaldehyde¹³ and transferred to nitrocellulose²³. Parallel untransferred lanes were stained with ethidium bromide and the location of the ribosomal RNA bands determined. Blots were prehybridized at 42 °C in 50% formamide (w/v), 1% Denhardt's solution, 0.2% SDS (w/v), 0.9 M NaCl, 50 mM NaH_2PO_4 pH 7.4, 5 mM EDTA and 100 μ g ml^{-1} carrier calf thymus DNA. The filters were hybridized to nick-translated pBOS5 DNA²⁴, washed and exposed to Kodak XAR-5 film. *b*, Excised stigmas and 1-mm sections of stylar tissue were metabolically labelled by submersion in a ^{14}C -amino-acid mixture as described elsewhere⁹. Isoelectric focusing analysis of radioactively labelled proteins and autoradiography were also as previously described⁹.

Approximately 2,000 independent clones were picked randomly from this cDNA library, and DNA from these colonies was then transferred to each of two nitrocellulose filters and hybridized with the appropriate probes¹⁴. Eight colonies were found to hybridize strongly with stigma-derived cDNA probe but not with seedling cDNA probe. Plasmid DNA was prepared from each of these eight colonies, and digests with the restriction endonuclease *Bam*HI were performed such that the cDNA inserts could be separated from the plasmid vector by gel electrophoresis. Cross-hybridization experiments performed on these digests indicated that the *Brassica* DNAs in all eight recombinant plasmids were homologous (results not shown). The plasmid containing the largest cDNA insertion, pBOS5, was chosen for use in all subsequent experiments reported here.

pBOS5 expression during development

To examine more directly the proposition that the inserts in plasmid pBOS5 and its relatives correspond to SLGG mRNA, the concentration of pBOS5-homologous mRNA was measured as a function of stigma development (Fig. 1). Northern analysis of RNA prepared from populations of staged stigmas reveals a prominent band ~2 kilobases (kb) long which cannot be detected in leaf and style tissue (Fig. 1*a*). This RNA species must be quite abundant in the stigma, as intense signals are obtained even when poly(A)⁺ RNA has not been purified. The pattern of expression of these sequences parallels the pattern of synthesis

Fig. 2 Nucleotide sequence and deduced amino-acid sequence of the cDNA insert in pBOS5. Sequences delineated by the indicated restriction sites were subcloned into the M13 vectors M13 mp10 and M13 mp11 (ref. 25). Sequencing was carried out by the dideoxynucleotide chain-termination method¹⁵ using a synthetic 17-mer as primer (New England Biolabs).

of SLGG in the stigma (Fig. 1*b*), a maximum level being observed 1 day before the flower opens. It should be emphasized that the stigmas of immature buds are self-compatible, so that fertilization with pollen which would normally induce an incompatible response is possible by mechanically opening the bud and placing such pollen directly on the stigma. As the buds develop, the stigmas become self-incompatible 1 day before anthesis, correlating with the observed peak concentration of pBOS5-homologous RNA.

An S-locus-specific glycoprotein

Although the previous results were consistent with the notion that pBOS5 contains sequences encoding SLGG, further tests were required to confirm the identity of this clone. Thus, the nucleotide sequence of the cDNA insert in pBOS5 was determined to guide strategies for the construction of chimaeric genes in which *Brassica* DNA could be transcribed and translated in *Escherichia coli* cells, in order to establish whether the resultant fusion protein would react with antiserum to authentic SLGG. Restriction endonuclease-generated fragments of the pBOS5 insert were subcloned into the M13 vectors mp10 and mp11 and the resulting single-stranded DNAs subjected to sequence analysis by the Sanger technique¹⁵.

Figure 2 shows the results of the nucleotide sequence determination. Although five of the six possible reading frames are blocked by multiple nonsense codons throughout the entire 1,284-base pair (bp) insert, the remaining reading frame translates into a polypeptide of 123 amino acids. The nucleotide sequence AATAAA, which has been implicated as a signal for the polyadenylation of mRNA¹⁶, is located downstream of the putative SLGG coding region, 11–16 bp from the end of the

Fig. 3 Subcloning of the pBOS5 cDNA insert into the pWR590 series of expression vectors. **a**, Generation of the pBOS5 L and S fragments by *Bam*HI/*Xho*I digestion. Arrows indicate the resulting direction of transcription in the chimaeric plasmid. **b**, Map of pWR590. Arrows indicate the direction of transcription. *lacZ'* denotes a shortened *lacZ* gene encoding about 590 amino acids. The expanded region following the *lacZ'* gene contains the poly-linker sequence. **c**, Nucleotide sequences of the expression vectors at the fusion junctions, and the expected translational products. nucs, nucleotides; aas, amino acids.

Methods. To construct expression plasmids of the *Brassica* cDNA sequence, the 745-bp (L) and 538-bp (S) *Bam*HI/*Xho*I fragments of pBOS5 were isolated from a 1% low-melting agarose gel and ligated to *Bam*HI and *Sac*I digests of pWR590, pWR590-1 and pWR590-2. The resulting six plasmid constructions, designated pWR590-L, pWR590-1L, pWR590-2L, pWR590-S, pWR590-1S and pWR590-2S, were used to transform *E. coli* SF8 cells²⁶.

cDNA insert presumed to have been derived from the 3' end of the mRNA. Such an interpretation of the sequence data implies that the 3'-noncoding region of the messenger is ~900 nucleotides long. Although such an extensive 3'-noncoding region is unusual, precedents have been noted in other eukaryotic mRNAs¹⁷. The absence of a poly(A) tract may be explained by the finding that the *Bam*HI sequences flanking both sides of the cDNA insert do not resemble the *Bam*HI linker sequence used to construct the cDNA clone. We presume that a *Bam*HI recognition site is located in the full-length cDNA sequence between the polyadenylation signal and the poly(A) tail of the messenger, such that this *Bam*HI site would be inserted into the pBR322 vector in place of the end provided by the linker sequence. Our inability to obtain clones with longer cDNA sequences is similarly explained by the presence of at least one additional *Bam*HI site in sequences internal to the mRNA.

Although incomplete, the predicted polypeptide has properties consistent with its corresponding to SLSG. Approximately 11% of the amino acids are basic and only 5% are acidic, in

Fig. 4 Western blot analysis of fusion proteins encoded by constructs in the pWR590 series of expression vectors. 'St' designates the lane with a stigma extract; the characteristic M_r heterogeneity⁸ of SLSG is shown. Designations above the other lanes indicate extracts from *E. coli* cells transformed with the corresponding pWR590 constructs. One band corresponding to the antigenic fusion protein is seen in lanes 1L. The mobilities of M_r standards are shown ($\times 10^{-3}$).

Methods. Transformed *E. coli* SF8 strains were grown overnight in the presence of 1 mM isopropyl thiogalactoside. Extracts were prepared by sonication in 7 M guanidine hydrochloride⁹, and aliquots equivalent to 500 μ l of culture were subjected to electrophoresis on 10% SDS acrylamide gels²⁷. The separated proteins were transferred electrophoretically to nitrocellulose membrane²⁸. Immunolabelling of nitrocellulose blots was as described elsewhere²⁹. The first-stage antiserum was raised in a New Zealand White rabbit by multiple intradermal injections of purified S_6 -specific glycoprotein. The second-stage probe was peroxidase-conjugated protein A.

keeping with the basic nature of most SLSG molecules analysed to date. Four potential *N*-glycosylation sites which follow the general rule of Asn-X-Thr/Ser (ref. 18) can be identified beginning at asparagine residues 28, 46, 96 and 103. Many serine and threonine residues are also potentially available for *O*-glycosylation.

The presumptive coding region of the cDNA insert is entirely contained within a fragment of DNA (fragment L in Fig. 3a) demarcated by recognition sites for the enzymes *Bam*HI (at positions 1-6) and *Xho*I (nucleotides 740-745). A family of three expression vectors (pWR590, pWR590-1 and pWR590-2) has recently been described in which foreign DNA may be inserted in all three possible translational reading frames into a polylinker region such that these exogenous sequences can be translated by *E. coli* cells into a fusion protein, the first 590 amino acids of which are supplied by a truncated *E. coli* β -galactosidase gene (ref. 19 and Fig. 3b). As illustrated in Fig. 3c, fragment L from pBOS5 theoretically would encode a fusion protein containing determinants encoded by the long open reading frame predicted by the DNA sequence data only when inserted into the vector pWR590-1.

Fragment L and fragment S, a *Bam*HI/*Xho*I fragment containing the remainder of the *Brassica* insert (Fig. 3a), were cloned into the pWR590 vectors such that all six possible reading frames of the *Brassica* cDNA could be assayed for their ability to promote the expression in *E. coli* cells of polypeptide determinants which could react with antiserum to authentic SLSG glycoprotein. Extracts prepared from cultures of *E. coli* transformed with the six constructs were probed with antibodies to SLSG (Fig. 4). It may be seen that in lanes 1L (pWR590-1L, see Fig. 3c), a band of relative molecular mass (M_r) ~85,000 reacts with the antiserum. As predicted, this band is not found in lysates from cells containing any of the other five chimaeric plasmids or the parental pWR590 vector. Furthermore, the size

Arrowheads indicate representative restriction fragments that segregate in correlation with the S_6 and S_{14} alleles. The nick-translated cDNA insert of pBOS5 was the probe. *b*, Southern analysis of *Bam*HI/*Pst*I digests of DNA from P_1 , P_2 , F_1 and an F_2 population derived by self-pollinating immature self-compatible stigmas of the F_1 heterozygotes. Electrophoresis was carried out longer than in *a* in order to resolve the higher- M_r restriction fragments. 6,6: S_6 homozygotes; 14,14: S_{14} homozygotes; 6,14: S_6S_{14} heterozygotes. The probe and arrowheads are as in *a*. *c*, Isoelectric focusing patterns of stigma extracts from the F_2 plants in *b*. The arrow indicates the S_6 -specific band and the bracket indicates the complex of bands characteristic of the S_{14} allele. The origin of electrophoresis (O) and the pH gradient are indicated. The gel was stained with Coomassie blue R250.

Methods. The S_6 and S_{14} homozygotes are inbreds maintained at Cornell. Incompatibility phenotypes were determined in F_2 plants by crossing to tester homozygous strains and by diallel analysis. The pollinated flower stigmas were stained with decolorized aniline blue and pollen-tube development monitored by fluorescence microscopy^{30,31}. DNA was prepared from ~0.25 g of leaf tissue by a modification of a rapid phage lysis protocol. Digests of genomic DNA were electrophoresed on 0.9% (w/v) agarose gels and transferred to GeneScreen filters (NEN)³². Filters were prehybridized and hybridized in 50% (w/v) dextran sulphate, 330 mM NaP_i, pH 7.0, 10 mM EDTA, 5% (w/v) SDS and 100 μ g ml⁻¹ carrier salmon testes DNA, at 67 °C. Washed filters were exposed to Kodak XAR-5.

of the prominent band is that expected for a fusion protein consisting of 593 amino acids from β -galactosidase and the polylinker region and 123 amino acids encoded by the *Brassica* cDNA clone.

Genomic pattern

Southern analysis of *Brassica* genomic DNA cleaved with a variety of restriction enzymes, including *Eco*RI, *Sal*I, *Xho*I, *Bam*HI and *Pst*I, revealed *S*-allele-associated restriction site polymorphisms. In each digest, several bands hybridized with

Fig. 6 Southern analysis of *Bam*HI/*Pst*I digests of DNA from different *S*-allele homozygotes of *Brassica*. The homozygous lines were obtained from the Gene Bank Facility at Wellesbourne, Warwick, UK, courtesy of Dr David Ockendon. The numbers above the lanes refer to the *S*-allele designations of the Gene Bank Facility. The probe is as in Fig. 5.

pBOS5. To determine whether these polymorphisms segregate with the *S* locus, DNA was prepared from an F_2 population obtained by the selfing of heterozygous F_1 plants derived from S_6S_6 and $S_{14}S_{14}$ homozygotes. Analysis of this DNA cleaved with *Bam*HI and *Pst*I showed that some pBOS5-homologous bands are common to all of the plants examined, but that others are clearly specific to the S_6 or S_{14} alleles (arrowheads in Fig. 5*a, b*). Heterozygous S_6S_{14} plants display a hybrid pattern. Similar results have been observed for 55 plants from this F_2 cross and for an additional 22 F_2 plants segregating for the S_6 and S_{13} alleles. In all cases, the restriction site polymorphisms revealed by the pBOS5 probe co-segregate with the *S*-locus genotype as determined by pollination analysis, and with the SLSG polymorphism as determined by isoelectric focusing. A prominent band with an isoelectric point of ~9.0 is present in S_6S_6 homozygotes (Fig. 5*c*), but is replaced by a series of bands only slightly basic in charge in homozygous $S_{14}S_{14}$ plants. Of the heterozygous plants examined, all synthesize both sets of SLSG molecules.

Finally, the restriction endonuclease-generated fragments of *Brassica* DNA homologous to pBOS5 in plants homozygous for each of 14 different *S*-locus alleles demonstrate patterns specific to each genotype (Fig. 6) and suggest a variability sufficient to account for the 50 or so *S*-locus alleles known in *Brassica* populations.

Discussion

Our results show that pBOS5, and presumably the seven other homologous cDNA clones we have isolated, contain sequences specifying an *S*-locus-specific glycoprotein (SLSG). This identity has been established directly by the demonstration that pBOS5 encodes SLSG-specific antigenic determinants. A chimaeric gene, in which the cDNA insert from pBOS5 is joined in-frame with the *lacZ* gene from *E. coli*, directs the synthesis in *E. coli* cells of a fusion polypeptide which reacts with antiserum against authentic SLSG. Furthermore, the characteristics of the mRNA from which pBOS5 was derived are consistent with a molecule capable of encoding SLSG. This mRNA species is found in stigma tissue, but cannot be detected by our methods in styles, leaf or seedling tissue. The concentration of this messenger varies as a function of the maturity of the stigma in parallel with the rate at which SLSG is synthesized. Finally, DNA sequencing studies suggest that the 2-kb RNA homologous with pBOS5 is of sufficient length to encode SLSG. Although

estimates of the relative molecular mass of SLSG are complicated by the fact that these macromolecules are heavily glycosylated²⁰, preliminary experiments using material in which the carbohydrate moieties have been chemically removed from SLSG suggest M_r of 40,000–50,000 (J.B.N., unpublished results). Accounting for the long 3'-noncoding region deduced from the sequence data, over 1,100 nucleotides of protein-coding information remains in the 2-kb mRNA, sufficient to encode a polypeptide of 45,000 M_r . Furthermore, the amino-acid composition of the predicted polypeptide is consistent with that reported for three SLSGs in *B. oleracea*²⁰.

As outlined above, several lines of evidence strongly suggest that SLSG is the product of the *S* locus. The clearest support is provided by the finding that polymorphisms in the SLSG molecule itself and restriction site polymorphisms in the vicinity of certain genomic DNA sequences homologous with pBOS5 co-segregate with *S*-locus alleles. DNA likely to encode SLSG is thus genetically at or very closely linked to the *S* locus. Even in the event of fortuitous linkage between SLSG-encoding sequences and *S*-locus sequences, the latter would therefore be accessible to molecular cloning by the use of chromosome walking procedures extending from pBOS5-related genomic fragments.

Note that only the subset of the genomic restriction fragments homologous with pBOS5 which are specific for the *S*-locus genotype can be shown to segregate with the *S* alleles in the analysis reported here. Thus, these experiments do not completely rule out the possibility that the gene for SLSG is located on a segment of DNA unlinked to the *S* locus. If this is so, the SLSG polypeptide specified by this unlinked segment must be modified in some manner by a different molecular product of the *S* locus. However, the bands which exhibit polymorphisms are, in general, those which hybridize most strongly to the pBOS5 probe, and are thus most likely to have served as the template for the transcription of SLSG message.

At present, the simplest hypothesis consistent with the data asserts that SLSGs are in fact the products of the *S* locus. This assumption may be tested directly by a future demonstration that the transformation of plants with cloned genomic DNA selected with pBOS5 can alter their incompatibility specificity.

We thank L. H. Guo and R. Wu for providing expression vectors pWR590, pWR590-1 and pWR590-2 before publication, and R. Wu and A. M. Srb for the use of their laboratory facilities in carrying out part of our work. This work was supported by a grant from the Cornell Biotechnology Program to J.B.N. and M.L.G., and by NSF grant PCM8118035 to M.E.N.

A cosmic-ray explanation of the galactic ridge of cosmic X-rays

C. L. Bhat*, T. Kifune* & A. W. Wolfendale

Physics Department, University of Durham, South Road, Durham DH1 3LE, UK

Recent observations¹ with the Exosat X-ray satellite have confirmed the existence of an apparently diffuse galactic ridge of emission extending over the inner Galaxy ($l = 320^\circ$ – 40°) and confined to about $\pm 2^\circ$ in galactic latitude. On the basis of measurements² carried out in the galactic plane at $l \approx 55^\circ$, we have proposed previously³ that the diffuse galactic X-ray flux known at that time could be understood in terms of the synchrotron radiation of cosmic-ray electrons in the galactic magnetic field. The more extensive Exosat measurements fit nicely into this picture and the X-ray-producing electrons can now be readily understood as being secondary to the ultra-high-energy protons, which are themselves generated in galactic objects as epitomized by the recently discovered^{4,5} Cygnus X-3. We show here that, on this model, the number of Cyg X-3-like objects present in the Galaxy at any one time, averaged over the past 10^3 yr or so, is ≈ 30 .

The first report of an apparently diffuse X-ray flux from the galactic plane seems to have been by Cooke *et al.*⁶ in 1969. The most recent¹ work, using Exosat for two-dimensional mapping, strongly supports the existence of the ridge, and Warwick *et al.*¹ estimate an overall galactic diffuse emission of $\approx 1 \times 10^{38}$ erg s⁻¹ in the energy range 2–6 keV.

Figure 1 reproduces some of the Exosat results, together with a profile of the synchrotron emission at 408 MHz from ref. 7. The bulk of the 408-MHz radiation is due to GeV cosmic-ray electrons interacting with the galactic magnetic field. The similarity in the X-ray emission distribution with the synchrotron radiation profile is encouraging for our model but not conclusive, of course, because of the significant differences in spatial distributions of the X-ray-producing electrons ($\sim 10^{13}$ – 10^{15} eV) and the GeV electrons responsible for the 408-MHz radiation; the z (height above the galactic plane) distributions are very different.

The normalization in Fig. 1 is made at the minima in the observed X-ray profile in the region of $l \approx 30^\circ$ and 330° , because these low values should more closely represent the genuinely diffuse X-ray component between the sources (we consider that the minima at $|l| < 30^\circ$ are contaminated by contributions from unresolved discrete sources). The corresponding total X-ray emission is lower by a factor of ~ 2 than the estimate made by Warwick *et al.*¹ and is thus $\sim 5 \times 10^{37}$ erg s⁻¹. Another difference between our approach and that of Warwick *et al.*¹ is that we believe that the 'dips' in the X-ray profile, rather than reflecting

Fig. 1 Longitude distribution of the 'diffuse' X-ray emission, in the range 2–6 keV, from ref. 1 (Exosat data); the dashed line represents the profile and the circles the minima. The units are $7 \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$ per beamwidth. Also shown is the 'model' that we adopted based on the 408-MHz radio profile at $b = 0^\circ$ (ref. 7), normalized to the X-ray flux minima at $l \sim 30^\circ$ and 330° . The patchiness in the observed X-ray emission probably comes from both the presence of unresolved discrete sources, which are difficult to allow for, and the fact that the ultra-high-energy electrons, producing the synchrotron X rays, have only a limited diffusion away from their sources during the average electron lifetime of $\approx 2 \times 10^3 \text{ yr}$ against radiative losses.

excessive absorption, correspond to regions of lower intrinsic emission as well as inter-source regions.

The magnitude of the absolute electron flux that is compatible with the observed X-ray emission is of the order of $\sim 10^{-24} \text{ cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ eV}^{-1}$ at 10^{14} eV , as inferred by Protheroe and Wolfendale⁸ to explain the then known diffuse X-ray flux^{2,3}. This electron flux corresponds to an injection spectrum having a roughly constant exponent from much lower energies and it is higher than that based on an extrapolation of the local electron spectrum, known only up to particle energies of $\sim 10^{12} \text{ eV}$. The argument advanced then⁸ to account for this apparent disparity was that we are not near enough to an ultra-high-energy electron source, at present, to measure the actual average galactic intensity, which was admittedly a rather *ad hoc* justification.

The new development that has strengthened the above argument, in particular for a significant contribution to the galactic X-ray ridge coming from the cosmic ray electrons, has been the discovery^{4,5} of ultra-high-energy γ rays, up to 10^{16} eV , from Cyg X-3, a binary system about 12 kpc from the sun. The γ rays are probably^{9,10} secondary to the protons which are first accelerated in the electromagnetic fields of one of the binary components (neutron star?) and then interact with the gas present in the atmosphere of the companion star. As a result, there will be electrons associated with the $\pi^\pm \rightarrow \mu^\pm \rightarrow e^\pm$ cascades corresponding to γ rays from the alternative π^0 -decay chain. The ratio of electrons to γ rays cannot be calculated accurately because of insufficient knowledge about the production region, but it is unlikely to be far from the factor 0.5 expected on the basis of kinematics, and we adopt this value here. We assume that the electrons can escape from the 'source region' and are not trapped by magnetic fields, a reasonable assumption in that the parent protons must have had near-rectilinear motion to preserve the γ -ray phase.

Concerning the energetics of the process, $\gamma \rightarrow e \rightarrow \text{X rays}$, we note that the γ -ray energy per decade from Cyg X-3 (1978 level⁴) is $\sim 10^{37} \text{ erg s}^{-1}$, centred on $5 \times 10^{14} \text{ eV}$, the energy required to give X rays in the middle of the detected range (2–6 keV). The X-ray energy is proportional to the square of the electron energy so that the progenitor-electrons will have energy $E_e \sim (4\text{--}7) \times 10^{14} \text{ eV}$, corresponding to the Cyg X-3 output of $0.5 \times 3 \times 10^{36} \text{ erg s}^{-1}$, that is, $1.5 \times 10^{36} \text{ erg s}^{-1}$.

If, as is likely, Cyg X-3-type sources represent a typical galactic population, such as pulsars, supernova remnants and

H II regions, and have a spatial distribution similar to that of the GeV cosmic-ray electrons¹¹ responsible for the radio synchrotron emission—a peak intensity of about twice the local value at a galactocentric distance $R = 6 \text{ kpc}$ —then the longitude distribution will be similar to that denoted by I_{408} in Fig. 1.

As was pointed out earlier, the total energy requirement in electrons is $\sim 5 \times 10^{37} \text{ erg s}^{-1}$ to account for the Exosat X-ray ridge so that there should be ~ 30 sources contributing, each emitting $\sim 1.5 \times 10^{36} \text{ erg s}^{-1}$ for $E_e \sim (4\text{--}7) \times 10^{14} \text{ eV}$. Note that this is not necessarily the number 'switched on' at present because the mean lifetime of the electrons due to the synchrotron losses in the galactic magnetic field is $\sim 2 \times 10^3 \text{ yr}$ at $E_e \sim 5 \times 10^{14} \text{ eV}$. Thus, this number corresponds to the average value over a time of this order.

The number appears to be large but is not implausible, as is evident from the following observations. (1) There is a suggestion¹² that Cyg X-3 has been considerably stronger in the past and the ultra-high-energy photon flux ($\sim 10^{15} \text{ eV}$) may have decreased by a factor as large as ~ 80 in the past decade only¹³, for which the data are available. (2) A source (LMC X-4), stronger than Cyg X-3 by a factor ~ 20 , has been reported¹⁴ in the Large Magellanic Cloud. (3) Cosmic-ray anisotropy measurements at $> 10^{15} \text{ eV}$ suggest that Cyg X-3 is not unique and that there may be up to 10 similar sources in the Galaxy at present¹⁵. Similarly, at lower energies, between 1 and $3 \times 10^{13} \text{ eV}$, the recent anisotropy measurements¹⁶ at Baksan Valley and Norikura indicate¹⁷ an 'excess' near Right Ascension (RA) $\sim 300^\circ$ with respect to the general flow of particles from RA: $40^\circ\text{--}100^\circ$. If interpreted as due to γ rays, this excess leads to an upper bound of ~ 70 on the number of sources operating in the Galaxy at present (see ref. 17). (4) A recent analysis of muon-poor showers by the Lodz group¹⁸ indicates an excess of 1–2% from the galactic plane at $\sim 2 \times 10^{16} \text{ eV}$, a result which is consistent with the presence of 10–15 Cyg X-3-like sources in the Galaxy at the present epoch¹⁷.

Finally, we consider the latitude dependence of the X-ray flux due to the cosmic-ray electrons. The short lifetime of these electrons ($\sim 2 \times 10^3 \text{ yr}$) means that they will rarely travel beyond 100 pc from their production points. Now the z distribution of the sources is probably of a similar magnitude (young stars have a scale-height $z_1 \sim 70 \text{ pc}$; (ref. 19), so that the z distribution of the energetic electrons is unlikely to be wider than that derived for the X-ray emissivity by Warwick *et al.*¹ from the experimental data.

All we now need is a test for the present hypothesis. The electrons, produced by the decay of charged pions, will have a differential exponent γ_d of 1.8 (for Cyg X-3 γ rays) to 2.8 depending on whether the target material, where the pions are produced, is thin or moderately thick. This exponent is likely to hold for electron energies of up to a few times 10^{15} eV , after which it may steepen sharply, as suggested by the spectral cutoff seen⁵ in the Cyg X-3 γ rays. As the synchrotron X rays ($< 10 \text{ keV}$) are produced by electrons of energy $10^{14}\text{--}10^{15} \text{ eV}$, we expect them to have a power-law spectrum with $\gamma_d = 1.4\text{--}1.9$. The observed spectrum may actually be steeper by $\Delta\gamma_d \approx 0.5$ because of the shorter lifetime of the higher energy electrons. The Exosat spectral data¹ seem to be consistent with thermal bremsstrahlung ($kT \sim 4\text{--}20 \text{ keV}$) or with a power law ($\gamma_d = 1.1\text{--}4.6$), and our prediction is in the middle of this range. It is to be hoped that better-quality spectral measurements will soon become available on the diffuse X-ray component and will further constrain the model spectrum.

The observation of the exponent as predicted here would go a long way towards establishing the phenomenon or, if the observed spectrum were steeper, in enabling an upper limit to be placed on the cosmic-ray electron contribution. In a sense, this test is complementary to the prediction by Rana *et al.*¹² of the presence of hard X rays, in the region of 100 keV, at high galactic latitudes. These X rays are likely to be due to synchrotron radiation by electrons, which are themselves produced in the halo following collisions of ultra-high-energy γ rays from Cyg X-3-like sources with the 3K radiation photons.

The supersonic solar wind possesses a variety of simple small scale (<10-min observation duration) phenomena, including discontinuities^{1–3} and magnetic holes^{4,5}. We report here recent AMPTE-UKS⁶ (Active Magnetospheric Particle Tracer Explorer–UK Satellite) observations, however, which reveal a dramatic new complex structure within the solar wind flow. In the plasma and field observations of this magnetic hole/current sheet system, the layers surrounding the strong rotation in the magnetic field contain compressed and heated solar wind, an enhanced field strength and considerable wave activity. The interior region shows strong ion heating but with ambient densities and a fluctuating magnetic field which dips to low values. The bulk flow velocity inside is deflected sharply from the anti-sunward direction, but not in the direction predicted by magnetic stresses across the boundary. The structure is expanding in thickness and is relatively young. The source of momentum and energy for this event remains unclear, and could even be magnetospheric.

Most structures observed by *in situ* satellite measurements in the collisionless solar wind plasma have relatively simple, monotonic profiles and are either passive, convecting entities or shocks. The present observations seen by the AMPTE-UKS reveal an apparently more active current sheet. An important aspect of this work is the combination of high-time resolution three-dimensional particle data and wave data with the traditional magnetic field analyses on which earlier studies have been based. Recent, independent work⁷ using the ISEE spacecraft reports eight events which are very similar to the one presented here and provides a complementary range of data analysis.

Figure 1 displays five minutes of field and bulk plasma data taken in the solar wind on 30 October 1984. The spacecraft was

Fig. 1 Solar wind observations taken on 30 October 1984 by the AMPTE-UKS. Panels give (top to bottom) the magnetic field strength, latitude and azimuthal direction in geocentric solar ecliptic (GSE) coordinates (the sunward direction is $\theta = 0$, $\phi = 0$ with $\theta = 90$ being northward and $\phi = 270$ downward), electron number density, wave autocorrelator automatic gain control (AGC) level, ion flow velocity, flow latitudinal and azimuthal directions, and electron and ion temperatures. The electron measurements are based on individual spectra and could be averaged over one spin period (~ 5 s) to obtain the mean values. The ion parameters are taken on alternate spins when the ion instrument resolved either the solar wind component or uniform 4π coverage. The ion density, not shown, mimics n_e . The wave AGC level responds in successive factors of 2 of wave electric field amplitude in the 0.11–3.9 kHz band.

located in the dawn sector (approximately 09:30 LT) at a position relative to the Earth's centre of $11.3 R_E$ sunward, $9.7 R_E$ downward and $0.22 R_E$ northward out of the solar ecliptic plane, placing it some $1.2 R_E$ upstream of the point where the satellite crossed the Earth's bow shock 80 min earlier. The magnetic field data are 0.5-s averages. The electron data are based on individual spectra covering the range 12 eV–16 keV taken at ≈ 1 -s intervals, with moments computed on the assumption of an isotropic distribution. Departures from isotropy thus appear as 5-s spin-modulated moments. The ion data shown have a time-resolution of ≈ 10 s.

On a longer timescale, the solar wind preceding the event, and until the penultimate dashed vertical line in Fig. 1, was disturbed by the presence of backstreaming ion beams and/or diffuse ions, indicating a magnetic connection to the Earth's bow shock. The magnetic field showed large amplitude fluctuations, with $\delta|B| \approx 2$ nT, about a mean field of $\langle |B| \rangle \approx 7$ nT. The large southward to northward rotation in latitude of the

Fig. 2 Minimum variance component of the magnetic field (*a*) and corresponding ion velocity component (*b*). The normal direction is $\hat{n} \approx (0.38, 0.90, -0.22)$ in GSE (*x, y, z*) coordinates.

solar wind magnetic field from before to after the delineated event, seen in the second panel of Fig. 1, resulted in an exit from the ion foreshock, and a period of smooth solar wind with $\langle |B| \rangle \approx 5$ nT followed the interval shown here. The dashed vertical lines separate the obvious feature into three distinct regions.

The 'central' region is characterized by a varying magnetic field with several holes or depressions in field strength down to ≈ 1 nT. This is accompanied by hot electrons and even hotter ions, the latter dominating the total pressure here (see Table 1). The bulk flow shows a dramatic deceleration (from 400 to 150 km s⁻¹) and deflection (through $\approx 90^\circ$) from the ambient solar wind, resulting in a marked drop in bulk flow energy in the spacecraft frame of reference (see Table 1). Curiously the number density here returns to values comparable to those in the solar wind. The central region maintains rough pressure balance with the surrounding layers and is separated from them by a passive tangential discontinuity (the low central density eliminates the possibility of a shock transition).

'Edge' regions of enhanced field strength and density, accompanied by a partial deceleration, deflection and heating of the solar wind plasma but with little change in field direction,

Table 1 Pressures and energy densities (10^{-11} J m⁻³)

Parameter	Expression	Solar wind	Edge	Central
Magnetic pressure	$ B ^2/2\mu_0$	1.1	11	0.04–7.8
Ion thermal pressure	$n_i k T_i$	0.75	49	65
Electron thermal pressure	$n_e k T_e$	5.2	35	12
Normal bulk KE density	$\frac{1}{2} n_i 1.16 m_p V_n^2$	7.2	7.3	29
Transverse bulk KE density	$\frac{1}{2} n_i 1.16 m_p V - V_n \hat{n} ^2$	100	220	5.9

The ion densities used to compute this table were those actually measured and were a factor of 2–3 smaller than n_e due to differing experimental response/calibration.

* Assuming 4% helium by number.

Fig. 3 Hodogram of the ion bulk velocity in the minimum variance plane of the magnetic field. The \hat{x}' direction corresponds to the maximum variance eigenvector, $\approx (0.21, 0.14, 0.97)$ GSE, while \hat{y}' is the intermediate eigenvector $\approx (0.90, -0.41, -0.14)$ GSE. Note that the velocity deflection is not aligned with the magnetic field maximum variance direction.

surround the central region. The automatic gain control (AGC) level of the wave experiment in this region gives r.m.s. wave amplitudes of the order of 1 mV m⁻¹ across this low-frequency band. Such strong fields usually indicate the presence of significant wave-particle interactions. Fast shocks probably form the outer boundaries of these regions although it is difficult to determine the downstream flow well enough to test this with any confidence. The particle correlator experiment on the satellite had sufficient time during the later trailing edge to reveal modulations over a range of frequencies (0–3 kHz) in the count rate of ≈ 100 eV electrons. This similarity to the response seen at the Earth's (fast) bow shock supports our supposition of a shock at the outer boundary. Table 1 shows that the total (plasma plus field) pressure in these edge regions is comparable to that of the central section, and that both considerably exceed the exterior pressure.

A minimum variance analysis of the field yields a well-defined normal direction (intermediate/minimum eigenvalue ≈ 4), \hat{n} , although Fig. 2 reveals quite strong fluctuations in the normal component of B . Figure 2 also shows the component of the ion bulk velocity along this normal. The average value of ~ 125 km s⁻¹ yields an estimated thickness of 15,000 km for the entire 2-min event. There is also a suggestion that the magnitude of V_n increases on entrance and decreases on exit, implying an expansion of the region by ± 50 –75 km s⁻¹. This interpretation is dependent on the normal direction which, given B_n from Fig. 2, may be inaccurate. Nonetheless, combining the expansion speed and thickness yields a maximum age of ~ 2 min for this active phase of the current sheet.

Figure 3 completes our analysis by displaying the ion bulk velocity in the plane of the current sheet. The large deflection of ~ 500 km s⁻¹ occurs primarily along the (\hat{y}') intermediate variance direction. Tangential stress balance, however, (if $B_n \neq 0$) predicts that ΔV should be along the maximum variance direction \hat{x}' (parallel to $\pm \Delta B$). Indeed, Fig. 2 has already indicated an average B_n which is consistent with zero. This central flow cannot correspond to the simple magnetic reconnection picture⁸ nor to that expected in smaller scale flux transfer events⁹ and must be bounded by purely tangential discontinuities. We conclude that the flow is driven predominantly by a strong pressure gradient within the sheet itself. Figure 4 summarizes the various field and flow directions deduced above.

The momentum and energy source responsible for the remarkable deflection and heating of the solar wind seen in this event

Fig. 4 Sketch of the geometry inferred from the data for the current sheet system, including the $(\hat{x}', \hat{y}', \hat{n})$ variance coordinate system of the magnetic field, \mathbf{B} (thin arrows), along with the current density, \mathbf{j} (cylindrical arrows), and bulk flow direction of the solar wind, \mathbf{V}_{sw} , and its deflection, ΔV , within the sheet (double arrows).

is not clear. This pressure pulse could have been generated by a fortuitously recent burst of magnetic reconnection located within the current sheet but some distance away from the satellite. On the other hand, we cannot eliminate the possibility of magnetospheric influence, most probably at the bow shock or within the magnetosheath. Tracing backwards along the velocity vector in the central region we reach a point of intersection with the bow shock (based on a fit to the bow shock¹⁰ normalized to its crossing 80 min earlier the same day). The time required to traverse this distance ($\sim 3.75 R_E$) is longer than our estimated maximal age, but only by 7%, which is well within our uncertainties in age, direction and bow shock position. Thomsen *et al.*⁷ discuss thoroughly (and cast doubt on) a variety of possible source hypotheses for their observed events.

Our data show a solar wind current sheet containing a strong, young pressure pulse which forces it to expand and drives a flow within the sheet itself. The hot, deflected interior is dominated by ion thermal pressure, and is separated from the ambient solar wind by regions of shocked or compressed solar wind. We have no explanation of the near solar wind densities inside the sheet, although initial compression/heating followed by the sheet's expansion may have conspired to provide this as a coincidence. We have not succeeded in identifying the energy source or triggering mechanism, which could be either magnetospheric or interplanetary in origin.

We have seen other examples in the AMPTE-UKS data set which display similar features to those presented here. A previously reported solar wind event¹¹ also showed some of the same characteristics.

We thank V. Formisano and our AMPTE-IRM colleagues from FRG for useful discussions, also Michelle Thomsen for comments and pre-publication material. We are indebted to Trefor Edwards, whose suspicions were aroused while watching the real-time AMPTE-UK data displays on 30 October 1984.

A gravitational analogue of Faraday rotation

Tsvi Piran*† & Pedro N. Safer*

*Racah Institute of Physics, The Hebrew University, Jerusalem, Israel
†Institute for Advanced Study, Princeton, New Jersey 08540, USA

In an effort to shed some light on the problem of nonlinear interaction of gravitational radiation we have studied the behaviour of cylindrical gravitational waves in vacuum. When only one mode of cylindrical gravitational waves is present, the well known solution is the Einstein-Rosen¹ waves which do not display any nonlinear behaviour. The general solution of two modes is unknown. To study it we express the cylindrical Einstein equations in a characteristic form and obtain an analytical approximation and a numerical solution for the general evolution of cylindrical waves. We report here that the propagation of these waves displays a reflection of ingoing to outgoing waves (and vice versa), combined with a rotation of the polarization vector between the + and × modes. The latter effect is a gravitational analogue of the electromagnetic Faraday rotation.

The general cylindrical Kompaneets Jordan Ehlers line element^{2,3}

$$ds^2 = e^{2(\gamma-\psi)}(dt^2 - dr^2) - e^{2\psi}(dz + \omega d\theta)^2 - r^2 e^{-2\psi} d\theta^2 \quad (1)$$

involves three functions ψ , ω , and γ , of r and t only. ψ and ω represent the two dynamical degrees of freedom of the gravitational field, + and × respectively; while γ plays the role of the total gravitational energy⁴. The Einstein equations in vacuum

$$\psi_{,tt} - \frac{\psi_{,r}}{r} - \psi_{,rr} = (e^{4\psi}/2r^2)(\omega_{,t}^2 - \omega_{,r}^2) \quad (2)$$

$$\omega_{,tt} + \frac{\omega_{,r}}{r} - \omega_{,rr} = 4(\omega_{,r}\psi_{,t} - \omega_{,t}\psi_{,r}) \quad (3)$$

$$\gamma_{,r} = r(\psi_{,t}^2 + \psi_{,r}^2) + \left(\frac{e^{4\psi}}{4r}\right)(\omega_{,t}^2 + \omega_{,r}^2) \quad (4)$$

$$\gamma_{,t} = 2r\psi_{,r}\psi_{,t} + \left(\frac{e^{4\psi}}{2r}\right)\omega_{,t}\omega_{,r} \quad (5)$$

can be cast into a simpler characteristic form. To do so we define the ingoing and outgoing coordinates $u = \frac{1}{2}(t-r)$, $v = \frac{1}{2}(t+r)$; and the ingoing, I_+ , I_\times and outgoing, O_+ , O_\times amplitudes

$$I_+ = 2(\psi_{,t} + \psi_{,r}) \quad (6)$$

$$O_+ = 2(\psi_{,t} - \psi_{,r}) \quad (7)$$

$$I_\times = \frac{e^{2\psi}}{r}(\omega_{,t} + \omega_{,r}) \quad (8)$$

$$O_\times = \frac{e^{2\psi}}{r}(\omega_{,t} - \omega_{,r}) \quad (9)$$

The indices + and × denote the respective polarizations. With these definitions equations (2)-(3) become a set of four, first-order, coupled equations (R. F. Stark, personal communication):

$$I_{+,u} = \frac{I_+ - O_+}{2r} + I_\times O_\times \quad (10)$$

$$O_{+,v} = \frac{I_+ - O_+}{2r} + I_\times O_\times \quad (11)$$

$$I_{\times,u} = \frac{I_\times + O_\times}{2r} - I_+ O_\times \quad (12)$$

$$O_{\times,v} = -\left(\frac{I_\times + O_\times}{2r}\right) - O_+ I_\times \quad (13)$$

These equations are supplemented with the boundary conditions

Fig. 1 Evolution for large r . The initial data are O_{+0} and I_{x0} . The initial waves propagate freely, until they cross each other. In the interaction region, O_+ and O_x rotate and a small amount of I_{x0} is converted to I_+ (see equations (17)–(20)). When leaving the interaction region, the rotation stops, and the ingoing and outgoing waves include both polarizations.

at the origin

$$I_+ = O_+ \quad \text{and} \quad I_x = -O_x \quad \text{at } r=0 \quad (14)$$

The initial conditions for equations (10)–(13) can be given either on a space-like hypersurface or on two null hypersurfaces, the latter being the simplest.

The first term on the right-hand side of equations (10)–(13), couples the ingoing and outgoing waves with the same polarization, giving rise to the usual cylindrical reflection. At $r=0$, this reflection is complete, and the ingoing waves turn into outgoing ones.

The other term describes a nonlinear interaction between the two polarizations. To investigate the nature of this interaction, we consider a large enough r , so that we can neglect the first terms in the right-hand side of equations (10)–(13). In this approximation, the solution of equations (10)–(13) becomes

$$I_x(u, v) + iI_+(u, v) = (I_{x0}(v) + iI_{+0}(v)) \exp \left[i \int_{u_0}^u O_x(u', v) du' \right] \quad (15)$$

$$O_x(u, v) + iO_+(u, v) = (O_{x0}(u) + iO_{+0}(u)) \exp \left[i \int_{v_0}^v I_x(u, v') dv' \right] \quad (16)$$

$I_{+0}(v)$, $I_{x0}(v)$, $O_{+0}(u)$ and $O_{x0}(u)$ are the initial conditions given on an outgoing ($u=u_0$) and an ingoing ($v=v_0$) null hypersurface respectively. When I_x is present, O_+ and O_x will oscillate according to equation (16) with a phase difference of $\pi/2$. This means that if the initial outgoing wave is linearly polarized its polarization vector will rotate as it propagates through the $I_x \neq 0$ region. The same is also true for the incoming waves (equation (15)).

For example, consider the case where $O_{x0} = I_{+0} = 0$ and $|O_{+0}| \ll |I_{x0}|$. I_x almost does not change:

$$I_x(u, v) \approx I_{x0}(v) \quad (17)$$

O_+ and O_x oscillate when the O_+ wave crosses the $I_x \neq 0$ region

$$O_+(u, v) \approx O_{+0} \cos \left(\int_{v_0}^v I_{x0}(v') dv' \right) \quad (18)$$

and

$$O_x(u, v) \approx -O_{+0} \sin \left(\int_{v_0}^v I_{x0}(v') dv' \right) \quad (19)$$

The appearance of O_x causes a conversion of a small part of I_x to I_+ and if $|O_{+0}| \ll 1$ we have

$$I_+(u, v) \approx -I_{x0} \int_{u_0}^u O_{+0} du' \sin \int_{v_0}^v I_{x0}(v') dv' \quad (20)$$

Fig. 2 I_x , I_+ , O_x and O_+ obtained by numerical solution⁶ of the exact equations (10)–(13). The initial data are $I_{+0} = O_{x0} = 0$, $|I_{x0}| \gg |O_{+0}|$, $|O_{+0}| \ll 1$. Note that the vertical scale is not the same in the different pictures. The behaviour matches the approximated equations (17)–(20) very well.

Fig. 3 Numerical results for initial data containing only an ingoing, x polarized pulse. Radiation in the I_+ , O_x and O_+ waves appears, and these waves rotate. Note that O_x and O_+ are out of phase by $\pi/2$. After O_x and O_+ leave the region where I_x is present the rotation stops (the vertical scaling is different for each section).

This behaviour is displayed in Figs 1 and 2. After the waves cross each other the rotation stops and the polarization vector freezes.

In general, when both O_{x0} and I_{x0} are large, each wave will cause a rotation of the polarization vector of the other.

The rotation of the polarization vector is due solely to the nonlinear nature of the gravitational interaction, that is, to the terms on the right-hand side of equations (2), (3). In electromagnetism there is no such interaction. However, in the presence of a magnetic field and plasma, the polarization vector of an incident linearly polarized wave rotates—a phenomenon known as Faraday rotation. Here the ingoing waves (say), play the role of both the plasma and the magnetic field as they rotate the polarization vector of the outgoing waves propagating through them.

One has to worry now about the combined effect of all terms in equations (10)–(13). If the initial data contains only the $+$ mode the sole effect will be the cylindrical reflection of I_+ to O_+ . These are the Einstein–Rosen waves. More complicated

behaviour emerges when the \times mode is present in the initial data. We observe both conversion of I_+ to O_+ and I_\times to O_\times (via the first term in equations (10)–(13)) and rotation between I_+ and I_\times and O_+ and O_\times taking place simultaneously.

For example, an initial I_\times pulse will reflect some O_\times wave. This O_\times wave will, in turn, cause a rotation of some of the initial I_\times pulse into an I_+ pulse and by itself will rotate (due to the presence of I_\times) into O_+ (see Fig. 3).

Does this simple analysis overlook some features of the interaction of cylindrical gravitation waves, such as formation of singularities? To answer this question, with R. F. Stark, we have solved numerically equations (10)–(13). The exact solution (Figs 2, 3) demonstrate the validity of this simple picture and its completeness. A detailed description of these results will be given elsewhere⁵.

We thank S. Phinney and J. Katz for helpful discussions. This work was supported by NSF grant Phy. 84-07219 and by the BSF foundation.

Helium isotopes in North Sea gas fields and the Rhine rift

P. J. Hooker*, R. K. O'Nions & E. R. Oxburgh

Department of Earth Sciences, Downing Street,
University of Cambridge, Cambridge CB2 3EQ, UK

The popular assumption that all natural hydrocarbon accumulations are biogenic in origin has recently been questioned^{1,2} with the suggestion that deep source (mantle-derived) hydrocarbons may contribute to accumulated biogenically produced hydrocarbons, and also give rise to hydrocarbon deposits in unexpected parts of the crust. The possibility that deep-source volatiles are present in significant quantities in the hydrocarbon-bearing parts of the crust of western Europe is assessed here using analyses of ³He abundances in groundwaters and natural gas accumulations within the UK mainland and continental shelf. For comparative purposes, analyses are also presented for groundwaters from the southern part of the Rhine Graben, a region that has been relatively active tectonically, and the site of Tertiary and Quaternary volcanic activity. In contrast, the North Sea sedimentary basins and Central Graben have no recorded Tertiary or younger volcanic activity. Helium associated with North Sea gas fields and groundwaters on the UK mainland is dominantly radiogenic, produced by decay of U and Th in the continental crust, even where heat flow exceeds 100 mW m⁻². A minor component (<1%) of mantle-derived helium with primordial ³He, may be present in some gas fields close to the North Sea Central Graben. Further south along the more active part of the same fault system in the Rhine Graben this component reaches >15% in groundwater samples. Fault structures seem to be important for the transport of mantle helium through the brittle upper crust. The results are entirely consistent with a biogenic origin for North Sea hydrocarbons.

Table 1 and Fig. 1 show ³He/⁴He and He/Ne ratios for 10 natural gas samples from the UK shelf and mainland; analyses were made as described elsewhere³. Nine of the samples are from the North Sea basins including the Ninian, Frigg, Forties fields in the north, and Placid, Indefatigable, Viking, Doty, Hewett and Leman in the south, and one sample is from the Wytch Farm field in southern England. He/Ne ratios are high,

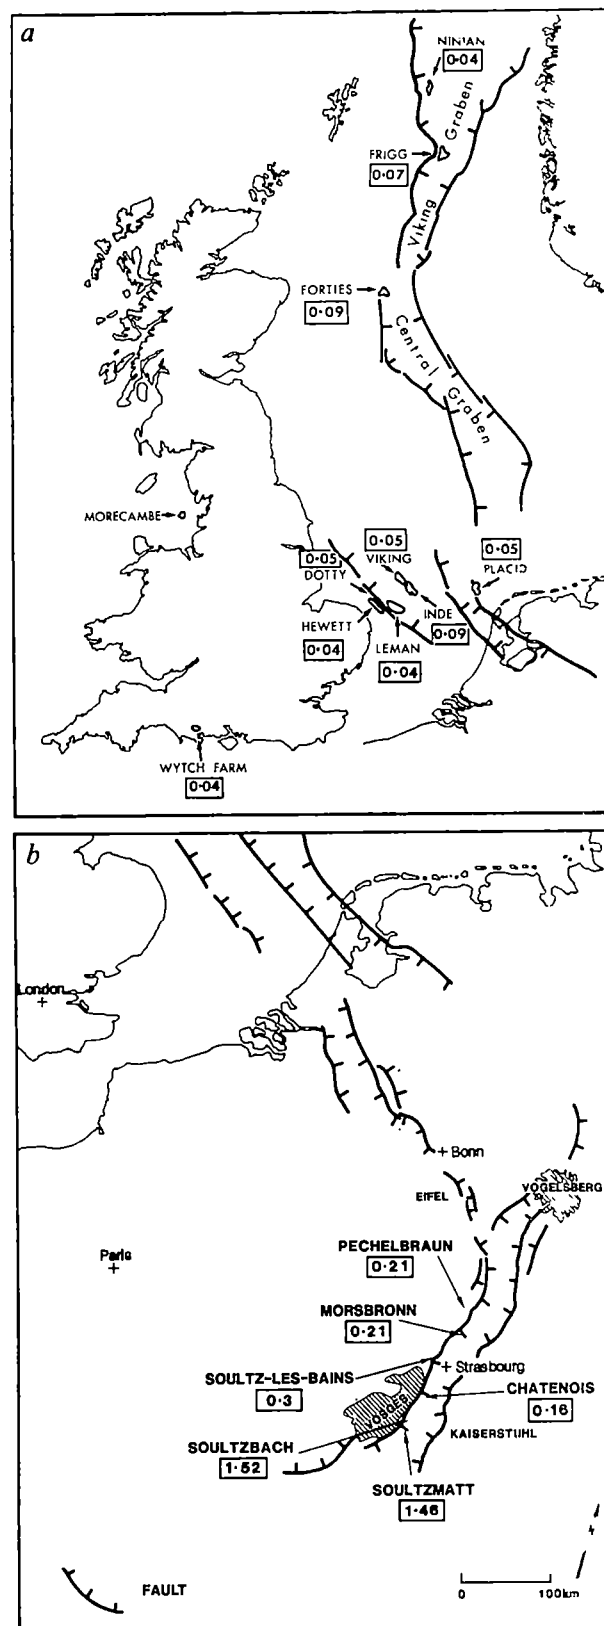

Fig. 1 a, Location of gas fields sampled for helium isotope analyses. b, Location of groundwater samples from the southern Rhine Graben. Numbers shown on maps are R/R_a values for samples analysed.

mostly >100, and indicate that any atmosphere-derived rare gas component is negligible in all cases except the Wytch Farm sample. Corrected $(R/R_a)_c$ ratios from the natural gas samples have a restricted range between 0.036 and 0.091, and where duplicate analyses have been made (Viking, Doty, Indefatigable, Frigg and Ninian) the ratios agree within several per cent. (R/R_a) is the ratio of the sample ³He/⁴He to that of the

R/R_a is the ratio of the sample $^3\text{He}/^4\text{He}$ to that of air (1.4×10^{-6}). The sample He/Ne ratios ($\pm 10\%$) were used to correct for air-derived helium in the sample by the expression $(R/R_a)_c = [(R/R_a)X - 1]/(X - 1)$ where X is $(\text{He/Ne})_{\text{sample}}/(\text{He/Ne})_{\text{air or water } 10^\circ\text{C}}$. For the gas samples $(\text{He/Ne})_{\text{air}} = 0.288$ was used, and for the groundwaters $(\text{He/Ne})_{\text{water}} = 0.230$. Neon is regarded as being purely of atmospheric origin. Generally, errors in R/R_a are $\pm 3\%$ at the 95% level of confidence, in agreement with the comparisons afforded by the duplicates carried out on several of the hydrocarbon samples. The [He] values for the groundwaters have uncertainties of $\pm 10\%$.

atmosphere.) $^3\text{He}/^4\text{He}$ ratios of crustal helium sampled by groundwaters are similarly low. Samples from the Lincolnshire limestone aquifer in eastern England, the Marchwood borehole, Hampshire, and return waters from the Carnmenellis granite, artificially fractured as part of a Hot Dry Rock Project, have R/R_a values between 0.014 and 0.04 (Table 1, Fig. 2). The highest R/R_a values currently known from the UK mainland and shelf are from gas fields intimately associated with boundary faults to the Central Graben structure in the North Sea.

$^3\text{He}/^4\text{He}$ and He/Ne ratios are presented in Table 1 for 12 groundwaters from Alsace, several of which are currently exploited as mineral water sources. All samples have high He/Ne ratios, mostly > 100 , and have insignificant atmosphere-derived helium components, with higher and more variable R/R_a values ($0.14 < R/R_a < 1.5$) than those found on UK mainland and shelf. All of the Alsace samples show higher levels of ^3He -enrichment than any of the UK samples.

The presence of a small amount of mantle-derived helium in the continents should be recognizable even when diluted by very much larger amounts of radiogenic helium (Fig. 2). However, the estimation of its abundance depends critically on the precise R/R_a values assigned to the mantle and crustal components. The composition of the present-day mantle-derived component, typified by the release at spreading ridge axes, is well known, and more uncertainty surrounds the appropriate values for the radiogenic production ratio of helium in the crust. Early estimates of the production ratio⁴, which assumed the ^6Li (n, α) ^3H reaction to be the dominant ^3He -producing reaction, suggested R/R_a values for crustal helium of 0.1. More recent estimates⁵ of neutron-producing reactions in crustal rocks suggest a production value of $R/R_a = 0.02$, for typical continental

crust. In several situations, good agreement has been reported between the measured R/R_a values of helium and the predicted values for particular lithologies⁵. The above deductions are certainly consistent with the results reported for the groundwaters and for at least some of the hydrocarbon reservoirs in the UK, which contain helium derived from large rock volumes. Some departure from these 'typical' values is to be expected on the scale of individual minerals or fluid inclusions where large variations in Li abundance and in effective neutron flux, will occur; thus R/R_a values > 0.1 have been reported for particularly Li-rich minerals. Such high production ratios will not, however, be characteristic of large segments of continental crust, and the high values reported from Alsace are interpreted in terms of an admixture of mantle helium with crustal radiogenic helium. A few of the North Sea gas fields, particularly Forties and Indefatigable, have R/R_a values significantly greater than that predicted for crustal radiogenic helium, implying either a small component of mantle-derived helium mixed with 'normal' crustal helium, or the presence of crustal helium with an abnormal R/R_a value in the natural gas reservoir. The latter possibility is difficult to assess, but would presumably require that locally Mesozoic sediments have abnormally high Li-contents and that these are degassing preferentially, or alternatively Li-rich mineral components lose their helium selectively. In the absence of appropriate chemical information on the sediments themselves, this possibility cannot be excluded, but the close proximity and control of North Sea gas fields by fault structures, coupled with the observed large excesses in ^3He associated with similar structures in the southern Rhine Graben, suggests that a trace ($\sim 1\%$) component of mantle helium has entered the Forties and Indefatigable fields.

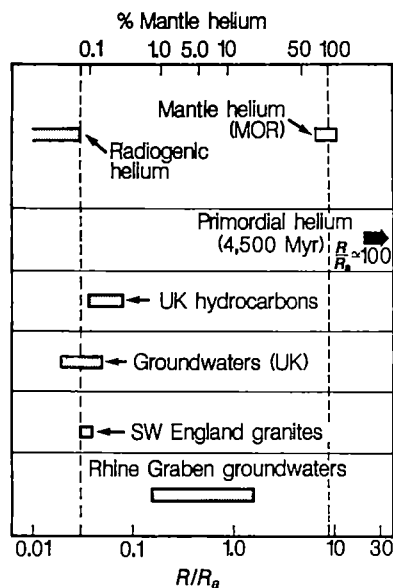

Fig. 2 The isotope composition of helium in samples from western Europe compared with radiogenic and mantle helium from mid-ocean ridges (MOR). $^3\text{He}/^4\text{He}$ ratios of samples (R) are compared with the $^3\text{He}/^4\text{He}$ ratio of the atmosphere, $R_a (=1.4 \times 10^{-6})$. The observed variations are interpreted as mixtures of radiogenic helium ($R/R_a < 0.03$) and mantle-derived helium possessing a primordial ^3He component with $R/R_a = 9$. The corresponding percentage of mantle helium on this basis is indicated at the top of the figure. The estimated composition of radiogenic helium is taken from ref. 5. Results for the Rhine Graben and UK hydrocarbons are from Table 1 and those for UK groundwaters are unpublished data from Cambridge and results of D. Hilton (personal communication). The south-west England granite data were obtained from a Hot Dry Rock experiment⁶.

The observed 50-fold variation in the R/R_a values of helium sampled from the UK and southern Rhine Graben raises the question of what factors control the transport of mantle-derived helium through the continental crust. The most obvious variables in the regional geology of the areas investigated are the heat flow, the presence of active faults associated with major rift structures, and the timing of the last volcanic episode within the area.

All helium results reported here from the mainland UK and others from south-west England⁶ and Lincolnshire (D. Hilton, personal communication) are from sites where the heat flow has been measured. Heat flow varies from $\sim 125 \text{ mW m}^{-2}$ in south-west England to $\sim 65 \text{ mW m}^{-2}$ in Lincolnshire⁷. R/R_a , however, remains close to 0.03 and shows no dependence on heat flow. This is the relationship to be expected in an old stable region where variation in heat flow depends largely on local variation in heat production in the crust. Although such variations in the abundance of U and Th do affect the heat flow they do not affect R/R_a , but only the total abundance of radiogenic helium. The heat flow in both the North Sea and the Rhine Graben is believed to be affected by deep fluid circulation⁸ and in the North Sea seems to vary with depth but in both areas may locally exceed 100 mW m^{-2} .

The igneous history of the three areas under discussion shows marked differences. Apart from Lundy in the English Channel, the southern part of the British Isles has not been affected by post-Mesozoic igneous activity. The same is probably true of the North Sea. The Rhine Graben, however, has a long history of activity⁹ and late Tertiary eruptions have occurred in the northern part of the Graben near the Eifel (11 Myr) and about 100 km south of Strasbourg at Kaiserstuhl (13 Myr). The highest R/R_a values came from localities close to the Kaiserstuhl. The whole of the Rhine Graben is seismically active today although the boundary faults close to which our samples were collected are relatively quiet; the greater part of the activity occurs away

from the margin fault, either just outside the Graben or clearly within it¹⁰. This difference has been tentatively attributed to the presence of fluids on the main boundary faults¹⁰. The Rhine Graben seismicity appears to weaken in intensity northwards and the Central Graben of the North Sea is nearly aseismic. The most intense seismic activity occurs in the Kaiserstuhl area where the highest R/R_a values are measured. All those samples that contain a component of mantle helium were collected near major faults. There is some suggestion that the highest mantle contributions occur where there is strongest activity. The very highest values come from an area of young igneous activity and high seismicity.

The importance of deep faults is that they are likely to provide transport paths for He through the brittle upper part of the crust which is too cool for diffusion to be effective. Elsewhere³ it has been suggested that the mantle-derived helium component associated with the high-temperature geothermal reservoirs at Larderello in northern Italy, has been advected to shallow ($< 6 \text{ km}$) levels in the crust by magma migration. In the Larderello region particularly, there is no recent volcanic activity at the surface, but a variety of lines of evidence indicate that a shallow ($\sim 7 \text{ km}$)-depth magma body is present and this is consistent with the large component of mantle helium observed near the surface. Similarly, in the southern Rhine Graben, it is possible that mantle helium is brought to comparatively shallow levels in association with magmas, and the faults act as channels for its escape to the surface. If it is real, the much smaller mantle helium component recognized in the North Sea may suggest either incompletely sealed deep fault or even possibly a signal of the onset of renewed activity.

The degradation of organic matter in sediments will be accompanied in space and time by the generation of radiogenic helium, which for typical sediments should have $R/R_a \approx 0.02$. Natural gases that have been sampled from the UK mainland and shelf have associated helium which is close to this value, consistent with a conventional source for the bulk of the hydrocarbons. Several of the North Sea gas samples have R/R_a values that are substantially higher than the expected radiogenic production ratio, which, if interpreted as an addition of a mantle-derived component, places an upper limit of 1% on the mantle helium component. In the case of the CH_4 -rich natural gases that border the Sea of Japan¹¹, the mantle-derived helium component may exceed 50%. Whether or not this might imply a volumetrically significant contribution of mantle CH_4 depends critically on the mantle $\text{CH}_4/^3\text{He}$ ratio and its modification during transport through the crust. On the basis of available observations on the volatile phase associated with oceanic basalts and mantle xenoliths^{12,13}, CH_4 must be considered as a minor species, far subordinate to CO_2 . Only if the dominant mantle-derived C species is CH_4 in continental regions, and $\text{CH}_4/^3\text{He} > 10^{10}$ is this source likely to be significant. Whereas there is the possibility of a trace of mantle-derived component in UK hydrocarbons, particularly close to the axial graben of the North Sea, there is no reason at present to conclude that the major gas CH_4 has anything but a conventional biogenic origin.

Different aspects of this research have been supported by the British Gas Corporation, EEC (contract no. EG-A-3-004-UK(N)) and the Royal Society. We thank Dr Meunier (University of Strasbourg) for assistance in sampling in Alsace. This is Department of Earth Science contribution no. 619.

Relics of H₂O fluid inclusions in mantle-derived olivine

Shoji Arai & Hisako Hirai

Institute of Geoscience, University of Tsukuba, Ibaraki 305, Japan

In olivine of upper mantle derivation, CO₂ is the most commonly reported species of fluid¹. Despite its great importance in the upper mantle², H₂O has rarely been reported (refs 3, 4 and E. Roedder, personal communication). Here we report that possible relics of H₂O-rich fluid inclusions have been found in olivine of dunite from the alpine-type Iwanai-dake complex, northern Japan. These inclusions now consist mainly of serpentine and brucite, which may be the products of the reaction, olivine + H₂O = serpentine + brucite, in a closed system. The abundance of such inclusions suggests that the Iwanai-dake complex may have been derived from the upper mantle in conditions in which some free H₂O was available, such as the mantle wedge above a subduction zone.

The Iwanai-dake peridotite complex was emplaced in the southern part of Kamuikotan zone, located at the central zone of Hokkaido. The Kamuikotan zone is characterized by the tectonic mixture of high-pressure (jadeite-glaucophane type) and ocean-floor type low-pressure metamorphic rocks⁵. An ophiolite complex with the basal harzburgite was found at Horokanai⁶, the northern part of the Kamuikotan zone, and was interpreted to be a slice of the Mesozoic oceanic lithosphere which had been consumed to give rise to the collision between the Eurasian plate and the North American plate (the Kurile arc) in the Miocene⁷. However, large quantities of ultramafic rocks, especially those at the southern part of the Kamuikotan zone including the Iwanai-dake complex, constitute, not ophiolitic sequences, but isolated peridotite complexes. The Iwanai-dake complex^{8,9} is composed mainly of roughly layered dunite and harzburgite of upper mantle origin, with very small amounts of chromitite and pyroxenites. Application of the olivine-spinel geothermometry and geospeedometry¹⁰ gives an initial equilibrium temperature of 810 °C (or a little higher) from which the complex had cooled by 200 °C at the rate of 10⁻²–10⁻⁴ °C yr⁻¹. The peridotites around Iwanai-dake are almost wholly devoid of serpentinization and the degree of serpentinization increases abruptly towards the margin of the complex, indicating the post-emplacment nature of the serpentinization. Dunite and harzburgite are strongly magnesian and contain olivines of Fo₉₅₋₉₁ and Fo₉₃₋₉₁, respectively, characterized by exsolution lamellae of chromian spinel⁸.

Olivine is also characterized by many tiny inclusions, which form arrays in thin section (Fig. 1). These inclusions were examined in a particular sample of dunite (IW-8407) composed of equant coarse (up to 1 cm diameter) olivine (Fo₉₄₋₉₃, Fo₉₃ on average) and euhedral chromian spinel (Cr/Cr + Al atomic ratio, 0.75).

Fig. 1 Photomicrograph of inclusions in olivine, taken in plane-polarized light. Inclusion arrays are sharply cut by the post-emplacment serpentine veins. Scale bar, 50 µm.

Fig. 2 Transmission electron micrograph of an inclusion containing serpentine, brucite and magnetite (indicated by S, B and M, respectively). Note that the inclusion is completely surrounded by host olivine. Scale bar, 1 µm.

Some inclusions crosscut the kink band, suggesting that they formed after recrystallization of the host olivine. The shape of an individual inclusion is typically columnar. The inclusion arrays are clearly cut by post-emplacment serpentine (PES, chrysotile-lizardite), but do not cut or distort the fine texture of the serpentine vein. An individual inclusion can be shown to be isolated in the host olivine (Fig. 1).

The ion-thinned foils were observed and analysed in JEOL 200-CX electron microscope¹¹. The inclusion (Fig. 2) is completely surrounded by the host olivine and has a clear-cut outline of hexagonal shape, forming a sharply faceted negative crystal (Fig. 2) elongated parallel to [100] of the host olivine. Electron diffraction (Fig. 3a, b) and semi-quantitative analysis revealed that serpentine (S in Fig. 2), which forms bundle and radial fibrous aggregates, and brucite (B in Fig. 2), which is a rhomboid extended along the inclusion wall, are the main constituents of the inclusion. Notably, the volume ratio of serpentine to brucite is approximately 4 (Fig. 2). Species of the serpentine mineral could not be distinguished. A minute grain of Fe-Ni alloy or magnetite was always found (Fig. 2).

Because the present inclusion is completely surrounded by the host olivine, it is unlikely to have formed as a result of an external source of water at temperatures low enough for serpentine to remain stable. It is also improbable that the inclusion of hydrous minerals represents an early stage of the PES of the rock, because the inclusion arrays do not affect the fine texture of the serpentine vein (Fig. 1). We know of no plausible mechanism for the formation of such inclusions in olivine at the even lower temperature that would prevail after the PES. Nor is the array of inclusions a partially healed veinlet of serpentine and brucite, as no traces suggestive of the hydration-dehydration stage before the PES (for example, the paragenesis of olivine + magnetite or ferritchromit) could be found. The most appropriate interpretation is that, when the temperature (and possibly pressure) decreased, the water vapour trapped before the PES reacted with the surrounding olivine to form hydrous minerals via reactions such as $2\text{Mg}_2\text{SiO}_2$ (olivine) + $3\text{H}_2\text{O} =$

Fig. 3 Electron diffraction patterns of serpentine (a) and brucite (b). Debye rings and streaks observed in a can be indexed as reflections of serpentine. A net-like pattern in the lower left-hand of a (indicated by arrows) is that of *hk0* of host olivine (shorter and longer arrows, *b** and *a**, respectively).

$\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_2$ (serpentine) + $\text{Mg}(\text{OH})_2$ (brucite)¹². This reaction gives a volume ratio of serpentine to brucite of ~ 4.4 (ref. 13), which is consistent with that observed (~ 4). Since magnesite was not found in the inclusions examined, the $\text{CO}_2/\text{H}_2\text{O}$ ratio of the fluid must have been very low.

The present relic H_2O -rich fluid inclusions show the characteristics of so-called secondary inclusions¹, which implies that they were formed by healing of the fracture in olivine which had been filled by water vapour. The inclusion was formed at temperatures $>400^\circ\text{C}$, below that at which the ordinary serpentinization had occurred¹², and after the main deformation stage, which occurred at high temperatures. It is probable that the Iwanai-dake complex was derived from the relatively low-temperature upper mantle where free H_2O was available. This situation could be most easily achieved at the mantle wedge^{14,15}, especially near the leading edge, above a downgoing slab, where free H_2O in addition to CO_2 may be generally available. For example, peridotite xenoliths from the Ichinomegata crater (400 km on the continent side of the Japan Trench)^{16,17}, northern Japan, derived from the hydrated mantle wedge beneath the North-East Honshu Arc¹⁸, are the only known mantle materials containing H_2O -bearing fluid inclusions^{3,4}. In contrast, other peridotite xenoliths containing almost pure CO_2 fluid inclusions were derived from the upper mantle free of underlying subduction zones⁴. Olivine in peridotites of the mantle wedge, if slowly cooled to low temperatures, would have inclusions of serpentine-brucite, serpentine-brucite-magnesite, serpentine-talc-magnesite and talc-magnesite-enstatite, depending on the $\text{H}_2\text{O}/\text{CO}_2$ ratio of the fluid¹⁹. Peridotites in which H_2O -rich fluid inclusions constitute the leading edge of the mantle wedge

(or the fore-arc mantle) may be emplaced as ophiolites or alpine-type masses²⁰ like the Iwanai-dake complex, during the arc-arc collision in Hokkaido in the Miocene⁷. Peridotites of the typical fore-arc ophiolite, such as the Papuan Ultramafic Belt²¹, would be expected to contain olivine with serpentine-brucite inclusions.

We thank Drs E. Roedder, R. J. Arculus, T. Fujii and M. Kimata for their suggestions.

Improved kerogen typing for petroleum source rock analysis

Stephen R. Larter & Joseph T. Senffle

Unocal Science and Technology Division, Unocal Corporation, Exploration Research, 376 South Valencia Avenue, Brea, California 92621, USA

The chemical characterization of kerogen (typing) is a routine part of petroleum exploration programmes¹. Traditionally, kerogen has been characterized on the basis of microscopy² and bulk chemical methods³, procedures derived from the coal characterization literature^{1,4}. These methods do not today, however, provide adequate resolution of the complex mixture of kerogen components encountered in source rocks from petroleum-bearing sedimentary basins⁵. Here we report an improved classification approach for kerogens at all maturity levels. The method is based on a quantitative pyrolysis-gas chromatography approach using a polymeric internal standard, polymethylstyrene, to directly determine the absolute concentrations of specific kerogen pyrolysis products. In particular, cross-plots of normal hydrocarbon, aromatic hydrocarbon and total hydrocarbon yields of kerogen pyrolysis are used to recognize eight separate nodes of kerogen composition.

Two major factors control the petroleum potential of any sediment at any maturity level: (1) the quantitative fraction of sediment that contains potential petroleum-related chemical structures, and (2) the efficiency of expulsion of these petroleum products from the source bed^{1,5}. The maturity level of organic matter in a sediment simplistically reflects its extent of reaction along the reaction coordinate system representing reaction converting sedimentary organic matter (immature) to oil (mature) and ultimately methane and graphite (post-mature).

The fraction of the sediment that contains catagenetically stable petroleum-related structures is correlated closely with the position of the sediment on the reaction coordinate system. Pyrolysis-gas

chromatography (pyrolysis-GC) is widely used both to elucidate the structure of kerogens^{5–9} and to type them according to chemical properties and physical characteristics^{5,6–14}, with a view, among other applications, to determining catagenic petroleum yield and composition¹. However, conventional pyrolysis-GC fingerprinting of kerogens is a rather subjective process and cannot easily resolve differences between the continuous series of mixed type II and type III kerogens often found in near-shore marine depositional settings. Ideally, kerogens should be characterized at the same molecular level, as is possible with rock extracts and crude oils; thus, full quantitation of all pyrolysis products (as may be possible with calibrated pyrolysis-mass spectrometric methods) is desirable. Here, we have used pyrolysis-GC to quantitate normal hydrocarbon yields from kerogens on pyrolysis, and these data are used to better define kerogen type and, hence, petroleum yield and type.

Normalized abundances of pyrogram (pyrolysis-gas chromatogram) components were obtained on a per-kerogen or per-carbon basis, using a polymethylstyrene internal standard that was added and mixed in dichloromethane solution with the extracted kerogen. Pyrolysis-mass spectrometry and thermogravimetric analysis showed that the standard polymer decomposed during pyrolysis, at temperatures well below the maximum temperature (800°C), to yield a monomer (methylstyrene) as predominant product. The use of a polymeric internal standard is necessary due to the nature of the pyrolysis system used, in which sample loss during instrument set-up sometimes occurs and where a volatile standard would be lost non-quantitatively from the sample before pyrolysis. The device is described in Fig. 1 legend and is documented elsewhere¹². Polystyrene has been used in quantitative pyrolysis-GC studies of soils¹⁵ but the common presence of styrene (the pyrolysis product of polystyrene) as a kerogen pyrolysis product would interfere with the use of polystyrene here. Methylstyrene, while a minor component of some coal maceral kerogen pyrolysates^{12,13}, provides a component that is generally at a low concentration in most pyrolysates, and which elutes chromatographically away from other peaks of interest in pyrograms of most source rock kerogens.

Fig. 1 Normalized abundance (by weight of kerogen) of aliphatic and aromatic hydrocarbons in low-maturity kerogen pyrolysates. The diagram represents a cross-plot of the abundance of C_7 - C_{25} normal hydrocarbons (alkenes plus alkanes) and of C_6 - C_8 alkylaromatic hydrocarbons (benzene, toluene, ethylbenzene, xylenes, styrene) obtained by pyrolysis at 800 °C for 20 s of up to 500 μ g of solvent-extracted kerogen. \square , Type I: alginites from Australia. Δ , Type II: Miocene, California; Triassic, North Sea; Jurassic, Paris Basin; Jurassic, North Sea; Tertiary, Alaska; Carboniferous, UK. \circ , Type III: Jurassic, North Sea; Miocene, Indonesia; Cretaceous, Canada. \times , Type IV: Carboniferous, UK.

Methods. The kerogens were pyrolysed on a platinum filament in flowing helium on a Chemical Data Systems 120 Pyroprobe, modified for use with capillary GC columns¹². Kerogen/poly-methylstyrene mixtures were placed on the cleaned pyrolysis filament in methanol suspension via a glass capillary tube; the methanol was evaporated before pyrolysis. The procedure used is described in ref. 12. GC analysis was performed via a splitter system, the pyrolysate being separated on a 50-m SP2100 capillary column programmed from 40 to 300 °C at 4 °C min⁻¹. Hydrocarbons were quantitated using a methylstyrene internal standard generated during the pyrolysis process from polymethylstyrene admixed with the kerogen. Automated peak area integration of the pyrograms was done on a microcomputer. Replicate analyses of aliquots of the samples allowed determination of the reproducibility of the method (error bars represent 2 σ variation about the mean). The kerogens used were all of maturity less than that equivalent to a vitrinite reflectance level of 0.8%. One standard unit approximately equals 0.25%, by weight, of kerogen.

Figure 1 shows the absolute yield of aromatic (expressed as total benzene, toluene and C_8 aromatics) and normal hydrocarbons (C_7 - C_{25} n -alkenes plus n -alkanes) for a variety of low-maturity kerogens. Component abundances were determined by automated peak recognition and integration on a laboratory microcomputer system. Interestingly, the absolute normal hydrocarbon content of several of the type II and III kerogens is similar. In general, it is the higher naphthenic contribution from marine organic matter that provides the increased hydrogen indices of marine kerogen systems. Replicate analysis reveals that some approach to accurate quantitation of kerogen pyrolysis products can be made rapidly in this manner and that the method may prove applicable to more general quantitative characterization of complex geopolymers.

While fingerprint approaches have been successfully applied to kerogen typing using pyrograms^{6,8-10,12,13}, it is the lack of high-resolution quantitative data that has precluded typing kerogens to the same level of resolution with which source rock bitumens or oils are characterized¹. Figure 2 shows pyrograms of several kerogens which we believe represent distinct molecular assemblages at low maturity levels. Figure 3 shows a cross-plot of a hydrogen index parameter (determined from elemental analysis data; compare with ref. 16) and the total organic carbon (TOC)-normalized abundance of C_9 - C_{30} normal hydrocarbons estimated from peak height data. It is the relative positions of the kerogens on this diagram, the pyrogram fingerprint character, and a knowledge of the petrographic properties of the kerogens that allow this more refined subdivision of the classical Tissot typing scheme³. The inclusion of petrographic and chemical data in the characterization of source rock kerogens is widely practised within petroleum geochemical circles¹ and is a critical requirement when quantitative assessments of source rocks are required in terms of volumes of oil sourced from a source bed⁵.

By directly determining the total reservoir of specific pyrolysis elements present in the kerogen at any maturity level in the manner described above, direct assessment of actual petroleum potential for any kerogen system becomes possible on a molecular level. Further, this method allows the discrimination of kerogens hitherto grouped together on the basis of elemental analysis or hydrogen/oxygen indices. Thus, in Fig. 2g, h, the two type III kerogens analysed, while petrographically vitrinite-dominated, are clearly different in detailed composition. Vitrinites from the deltaic system (Fig. 2g) have appreciable quantities of normal hydrocarbon precursors in the system while the vitrinite from a coal swamp environment (Fig. 2h) is paraffin precursor-depleted. In assessing hydrocarbon-generating potential for a kerogen assemblage, it is frequently difficult to deduce actual potential from bulk chemical analyses as many detailed compositions, some capable of generating components of high molecular weight, are possible for any given bulk chemical analysis.

The detailed composition of kerogen pyrolysates as a function of type has been extensively reviewed before⁸⁻¹³ with regard to normal hydrocarbon and hydrogen index variation, as summarized below and in Fig. 3. Type I kerogens (Figs 2, 3) are generally characterized at immaturity with high hydrogen indices but the thermal degradation products may be highly paraffinic (Ip), mixed paraffinic/naphthenic (Ipn), or naphthenic (In), depending on source facies^{6,12} (examples are shown in Fig. 2). Type II kerogens with intermediate hydrogen indices and relatively low paraffin contents (IIpn) are characteristic of kerogens from marine source beds containing dominantly amorphous organic matter derived from algal and bacterial sources². Kerogens from many clastic 'super-source rocks' fall into this category, examples being kerogens from the Kimmeridge Clay Formation (North Sea basins), Lower Cretaceous sediments from the North Slope basins of Alaska, Miocene sediments from the Tertiary basins of southern California, and Lower Jurassic sediments from the Paris Basin. Type II kerogens with intermediate hydrogen indices but high paraffin precursor contents (IIp) are generally associated with land plant-derived exinite-rich systems.

Fig. 3 Paraffin index/hydrogen index cross-plot. The figure shows a cross-plot of the summed abundance of the C_9 - C_{30} n -alkenes plus n -alkanes determined from pyrogram peak height data plotted against a computed hydrogen index derived from elemental analysis data in the manner of Orr¹⁶ (Rockeval units = mg hydrocarbons per g TOC). Although not a true hydrogen index determined analytically, this approach does allow sample comparison on a common matrix effect-free basis. Paraffin index is based on the pyrolysis-GC unit = 0.25% by weight. Representative kerogen types: Ip, torbanite (*Botryococcus*) kerogens, rich in alginite (samples 1, 2); Ipn, tasmanite (alginite)-rich kerogens (sample 3); In, resinite-derived materials (sample 4); IIpn, amorphinite-rich kerogens from source rocks containing marine organic matter (samples 5-11); II/IIIp, exinite-rich kerogens (samples 12-16); II/IIIpp, Carboniferous sporinites (samples 17, 18); IIIpp, vitrinite-rich kerogens from marine/deltaic shales (samples 19-26); IIIap, vitrinite-rich kerogens from coal swamps (samples 27, 28); IV, inertinite-rich kerogens (sample 29). p, Paraffin-dominated pyrogram; pn, paraffin/naphthene-dominated; n, naphthene-dominated; pp, phenol/paraffin-dominated; ap, aromatic hydrocarbon/phenol-dominated.

As described above, immature type III kerogens may have paraffin contents ranging from high (IIIp) to almost zero (IIIap); type IV sediments are characterized solely by lean aromatic hydrocarbon-dominated pyrolysates¹².

Molecular approaches to kerogen typing are still in their infancy, but together with bulk chemical and petrographic characterization methods, they provide an improved method for examining the chemically and physically complex mixtures that represent the mixed type II/III kerogens of many near-shore marine settings. It is these mixed assemblages that are the least well-defined using established approaches, yet are the most common organic facies found in many of the world's basins currently being explored. The general approach outlined here,

while far from resolving this critical problem, is believed to be a necessary step in the development of new high-resolution quantitative methods for source rock kerogen characterization.

We thank Dr Bruce Bromley for assistance with data acquisition software and Unocal management for agreement to publish these data. John Brown assisted with manuscript review.

Magnetostratigraphy and palynology demonstrate at least 4 million years of Arctic Ocean sedimentation

A. E. Aksu* & P. J. Mudie†

It has long been recognized^{1,2} that the Arctic Ocean has a major role in regulating the timing of Northern Hemisphere glaciations, global heat exchange and ocean circulation. Several recent studies³⁻⁷ have attempted to interpret the palaeoclimatic record in sediment cores from the Arctic Ocean, but conflicting ages have been reported for palaeoclimatic events dated by different methods³⁻⁶. To establish a consistent chronology for cores from the central Arctic Ocean, we performed detailed palaeomagnetic and palynological studies of three cores collected⁷ near the crest of the Alpha Ridge, and obtained radiocarbon dates from planktonic foraminifers isolated from 1-cm-thick intervals. Magnetic inclination values for these cores clearly record normal and reversed-polarity intervals that apparently correspond to the Brunhes and Matuyama magnetochrons; the longest core also includes polarity intervals typical of the Gauss and Gilbert magnetochrons. This chronology is confirmed by the first and last occurrences of pollen and dinoflagellate species that can be correlated with European^{8,9} and DSDP¹⁰⁻¹² chronostratigraphies dated by standard biochronological methods. Micromass radiocarbon dates for foraminifers indicate a sedimentation rate of ~1 mm per 1,000 yr. We believe that these data confirm a long (>4 Myr) chronology for the Alpha Ridge cores, the lithostratigraphy of which can be correlated over extensive areas of the western Arctic Ocean²⁻⁷, and more important, provide dinoflagellate and palynomorph data that indicate the validity of early chronology.

Previous chronostratigraphic studies of Arctic Ocean sediments have been hampered by (1) problems of core handling and storage prior to sampling⁶; (2) incomplete reporting of magnetic data^{3,5,6}; (3) lack of dateable calcareous and siliceous microfossils in the tertiary sediments⁵; and (4) uncertain validity of U/Th dates from hemipelagic muds³.

Our cores were obtained in conjunction with high-resolution seismic profiles from the 1983 CESAR ice station⁷ and they

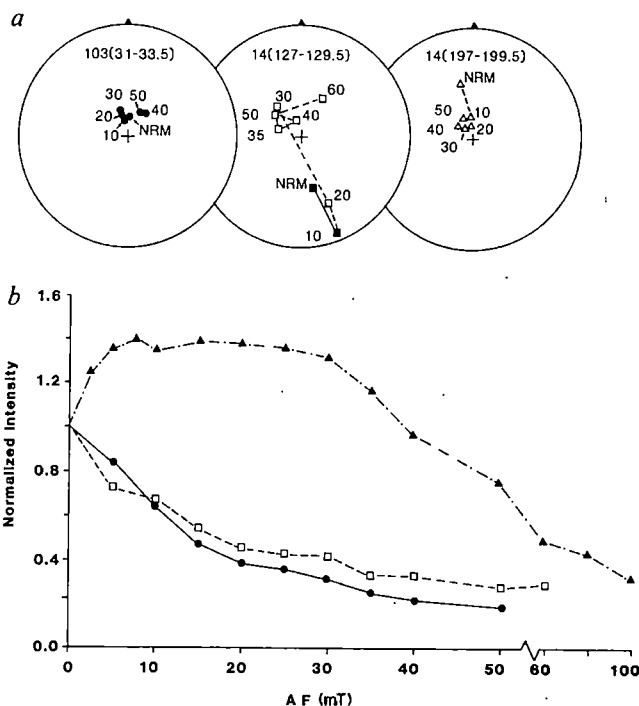

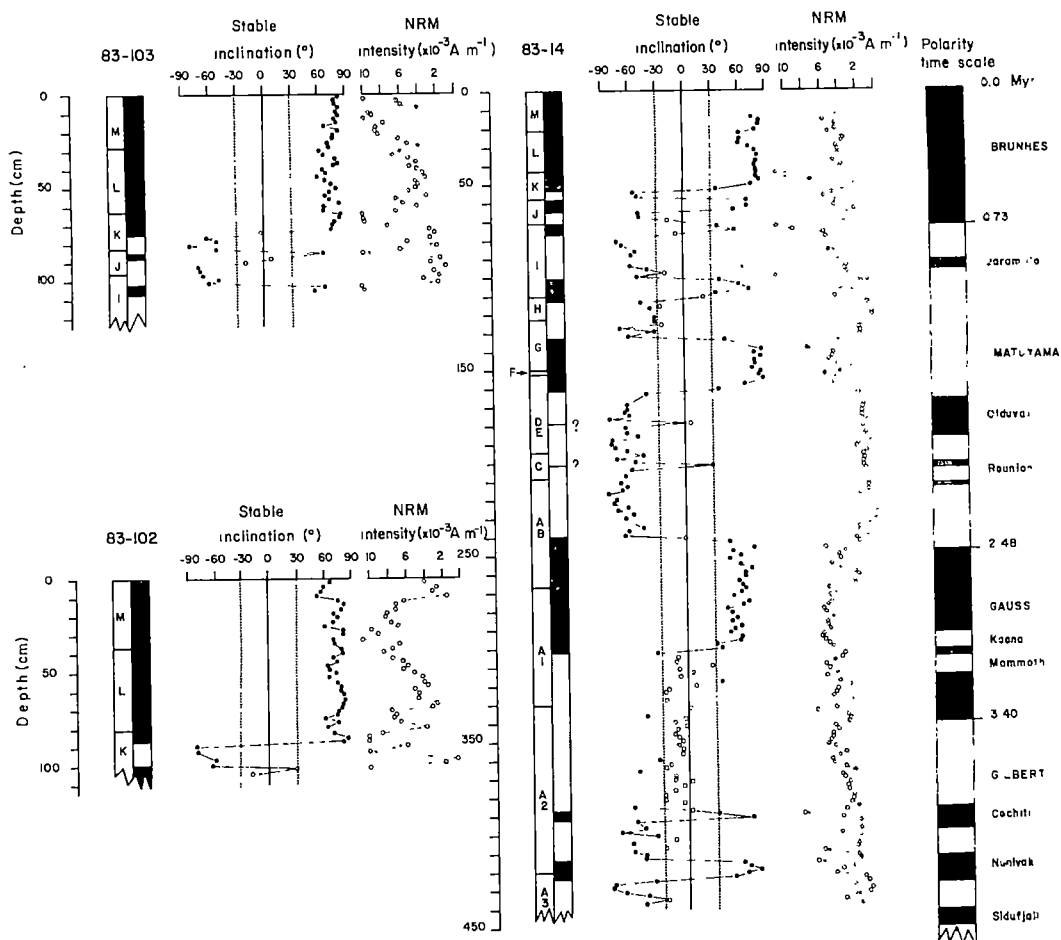

Fig. 1 Examples of directional response to AF demagnetization; open symbols indicate negative inclination, closed symbols indicate positive inclinations (a) and the normalized intensity response to AF demagnetization of these samples (b) where ● = 103 (31-31.5 cm), □ = 14 (127-129.5 cm), △ = 14 (197-199.5 cm).

were stored upright and prevented from freezing before laboratory studies. Two gravity cores, CESAR 102 (85°38.1' N, 111°07.1' W) and CESAR 103 (85°38.1' N, 111°07.0' W), and one long piston core, CESAR 14 (85°50.8' N, 108°21.6' W) were selected for study to ensure that a complete sequence of the surface sediments would be sampled (piston cores rarely recover the surface sediment layer). Cores were split 2-6 months after their recovery, and the sediments are free of post-coring disturbances due to desiccation, oxidation and previous sampling. Palaeomagnetic samples were taken using a plastic cylinder of 2.5 cm diameter¹³. After palaeomagnetic measurement, each sample was split at right angles to the vertical core axis, and the sediments were processed for palynological studies using HCl, HF and sieving methods¹⁴.

Palaeomagnetic measurements of the samples were made¹³⁻¹⁵ using a Schonstedt DSM-1 Digital Spinner Magnetometer. The intensity of the natural remanent magnetization (NRM) ranged from $0.1 \times 10^{-2} \text{ A m}^{-1}$ in normally magnetized samples to $0.5 \times 10^{-3} \text{ A m}^{-1}$ in reversely magnetized samples. Further magnetization measurements were made after alternating field (AF) demagnetization steps until the intensity values were reduced to <15% of the NRM, which usually occurred between 30 and 40 mT. As a precaution against excess demagnetization, however, all samples were stepwise demagnetized at 2.5, 5, 7.5, 10, 15, 20, 25, 30, 35 and 40 mT, with a few samples further demagnetized to 100 mT. Most normal and reverse stable remanence directions had associated precision parameters, k , with corresponding semi-cones of confidence, α_{95} , being less than 5°.

Figure 1 shows examples of the normalized intensity and directional response to AF demagnetization. Some of the remanent magnetization directional scatter may be caused by using the 'push-in' sampling method¹⁶. Normally magnetized core sections typically showed a steady decrease in intensity with demagnetization, accompanied by little directional response. Reversely magnetized sections typically showed an initial positive NRM that gradually changed to negative values with removal of the overprinted viscous remanent magnetization (VRM) after treatment at 10-20 mT. The steady decrease in normalized intensity suggested that the reverse stable remanence

Fig. 2 Downcore plots of stable inclinations (●) and NRM intensities (○). ○, Transition zones; □, samples in which a stable phase of magnetization was not achieved. A3–M, lithostratigraphic units⁷. Summary polarity logs for each core are based on all polarity changes that exceed +30 or -30° on their stable inclination; values of <30° are indicated as transitional. Polarity time-scale is from Harland *et al.*¹⁸.

intensity was weaker than the VRM. Some normally magnetized samples and about 20% of the reversely magnetized samples showed a progressive increase of intensity on treatment at 10 or 15 mT, followed by a steady decrease on demagnetization at 50 or 100 mT. Removal of the VRM caused little directional response in these samples.

Plots of stable inclination versus depth (Fig. 2) clearly reveal normal and reversed-polarity chrons like those observed in global magnetostratigraphies^{17,18}. The Brunhes-Matuyama boundary occurs around 71–77 cm depth in CESAR 103, at 85–90 cm in CESAR 102 and at 50–55 cm in CESAR 14. In all cores, this transition is sharp and is associated with a decrease in intensity of $0.8 \times 10^{-3} \text{ A m}^{-1}$ in the middle of lithofacies K. The Matuyama-Gauss transition is identified from the 239–244 cm depth in CESAR 14. Within the Matuyama reverse chron, four major positive subchrons occur in CESAR 14 and two are found in the gravity cores. All polarity changes are associated with large changes in intensity. The most prominent subchron (135–161 cm in CESAR 14) is tentatively correlated with the Olduvai normal event. The two short-lived positive events just below the Brunhes-Matuyama boundary are tentatively correlated with the Jaramillo event. The event at 102–109 cm depth in CESAR 14 may be either a split Olduvai subchron, with the lower part occurring at 135–161 cm, or the Gilsa event. The transition from Gauss normal to Gilbert reverse-polarity chrons is inconspicuous in CESAR 14. The stable inclination oscillated between 60° and 75°, then a 70° shift occurred, below which few samples showed clear stable remanence directions. The Gauss-Gilbert transition is therefore tentatively placed at ~300 cm depth.

Inclination values for the Brunhes and Gauss positive polarity chrons in CESAR 14 (Fig. 3) were strongly skewed towards high positive NRM values and showed little displacement with stepwise demagnetization. NRM inclinations in the reversed polarity Matuyama chron showed a slight skewness towards positive

NRM values, gradually displacing towards the negative values to form a well-defined peak at -45° to -75° by 40 mT. This behaviour demonstrated the successful removal of low-coercivity downward normal components, and the isolation of high-coercivity reversed-polarity components. It is clear that the viscous component is not totally removed before 30–40 mT demagnetization steps, and that samples show progressive directional response with each demagnetization step (Figs 1, 3). In most previous palaeomagnetic studies^{19–21} of Arctic Ocean sediments, samples were routinely demagnetized at 5–15 mT. The CESAR cores show that over 80% of the samples required demagnetization to 40 mT. Hence, insufficient demagnetization may account for the considerable scatter observed in inclination values reported previously.

Palynological studies of CESAR 103 and 14 were made on the samples used for palaeomagnetism measurements. Detailed data for CESAR 103 and initial results for CESAR 14 are documented elsewhere²²; systematic descriptions of the dinocysts (dinoflagellate cysts) are given by Mudie¹¹. The lithostratigraphy (facies A3 to M) and regional core correlations are documented elsewhere⁷. Here (Fig. 4) we show only the ranges of selected dinocyst, pollen and spore taxa in CESAR 14. Some notable similarities between the ranges of the marine dinocysts and those of terrestrial pollen and spores are evident: (1) The base of facies A2 is marked by the last appearance datum (LAD) or disappearance of two dinocyst taxa and five pollen/spore taxa, and one dinocyst taxon and one pollen taxon have their first appearance datum (FAD) in this interval. (2) Between the top of facies AB and C, three dinocysts and one pollen taxa have their LAD. (3) Between the top of facies G and the base of I, one dinocyst taxon disappears, and six dinocyst species and three pollen/spore taxa appear or reappear; the base of the Gramineae/Cyperaceae acme zone is found near the top of facies I. (4) In facies J to K, the calcareous dinoflagellate¹¹, *Thoracosphaera arctica* Gilbert and Clark, and several

in the early Pleistocene. These occurrences are in accord with our magnetochronology (Fig. 2). No FAD have been reported previously for *Picea mariana*, *Polytrichum* or *Peridinium faeroense* Dale, but at Site 611, these boreal taxa first become common at the onset of cooling at the Plio-Pleistocene boundary. The range of *T. arctica* has been dated as early Pleistocene in a number of other Arctic Ocean cores^{9,24} using palaeomagnetism and U/Th dating methods, and *O. centrocarpum* has an early Pleistocene acme zone in the Bering Sea.

(4) **Facies J to K.** At Site 611 and in the Bering Sea, *Spiniferites frigidus* has its FAD at or near the early/late Pleistocene boundary, which agrees well with our data for CESAR 14. In contrast, the FAD of *Votadinium calvum* and *Impagidinium patulum* and the base of the Gramineae/Cyperaceae acme zone occurs in the late Pliocene or earlier in the North Atlantic, *Nyssa* has its LAD in the late Pliocene of Europe and eastern Canada, and *Pseudotsuga* disappears at the top of the Cromerian Stage (~1 Myr) in Europe. Overall, correlation is not very precise for this interval in CESAR 14, but the palynomorphs definitely indicate a minimum middle Pleistocene age rather than the shorter (0.2 Myr) chronology proposed by Sejrup *et al.*³.

(5) **Facies L.** In Europe, *Juglans* has its LAD at the Holstein/Saalian boundary (~0.5 Myr), and Site 611, the tops of the *Quercus* and *Acer* acmes, and the LAD of *Tsuga* occur in the middle Pleistocene, indicating an age of 0.5 to at least 0.2 Myr, which agrees reasonably well with the magnetochronology proposed for CESAR 14.

Palynological correlation thus provides a chronology for the Alpha Ridge cores which generally supports the magnetochronology shown in Fig. 2. Hence, we conclude that the sedimentation rate on the Alpha Ridge has been very slow, about 1–1.5 mm per 1,000 yr, during the past 4.25 Myr. Further evidence for a very slow sedimentation rate is provided by tandem accelerator micromass radiocarbon dates from planktonic foraminifers (*Neoglobobulimina pachyderma* sinistral) that were hand-picked from the >150- μ m sediment fraction of CESAR 102 at 2–3 cm and 5–6 cm depth. Dates of >30,000 yr BP were obtained for both these samples (laboratory numbers Beta-12230 and Beta-12231, respectively). This slow deposition rate is in accord with previous magnetostratigraphic studies^{2,5,9,19,21}. These data conflict strongly with the short chronology and higher sedimentation rates (1–2 cm per 1,000 yr) obtained from dating by amino-acid epimerization³. In view of the potential importance of understanding the role of the Arctic Ocean in regulating the timing of Northern Hemisphere glaciations^{1,2}, detailed magnetostratigraphic and lithostratigraphic correlations and confirmation of dating using organic walled palynomorphs (which are not susceptible to carbonate or silica dissolution and are thus present in all the lithofacies) are important prerequisites for studying palaeoecological and isotope records from Arctic Ocean cores.

We thank C. Walls, D. C. Younger, L. Dobbin, K. McInnon and L. Ogden (Dalhousie University) for sediment sampling and preparation for laboratory measurements. The study was supported by DSS contract OSC83-00399 to Dalhousie University, and by GSC support for Project 820044. We thank S. M. Blasco and R. Fensome of the Atlantic Geoscience Centre, and Edward Irving for critical comments.

Fronde-like fossils from the base of the late Precambrian Wilpena Group, South Australia

Ian A. Dyson

School of Earth Sciences, Flinders University of South Australia, Sturt Road, Bedford Park, South Australia 5042, Australia

Late Precambrian metazoan fossils are at present known from at least 23 different regions in Africa, Asia, Australia, Europe and North America¹. The Ediacara fossil assemblage^{2,3} occurs widely in the Flinders Ranges, South Australia, near the base of the Rawnsley quartzite of the Pound Subgroup. This complex of soft-bodied organisms includes medusoid coelenterates, soft corals related to pennatulids, segmented worms, arthropods and other simple coelenterates^{4,5}. Here I report the discovery of frond-like fossils comparable to those of the Ediacara assemblage more than 3,000 m stratigraphically below the Ediacara Member⁶ of the Pound Subgroup. This discovery supports the placement of the base of the Ediacaran⁵ in South Australia at the boundary of the Wilpena Group and the Umberatana Group, a stratigraphic level which marks the termination of late Proterozoic glaciation in the Adelaide Geosyncline.

The Adelaide Geosyncline (Fig. 1) represents a sedimentary sequence that accumulated in response to a branching network of separate rifts with an overall meridional trend across the middle of the Australian continent^{7,8}. The late Precambrian Wilpena Group, a succession of predominantly terrigenous clastics deposited within the Adelaide geosyncline^{9,10}, rests conformably on glaciogenic sediments of the Umberatana Group¹¹. The Brachina Subgroup is the lower of two upward-coarsening sequences within the Wilpena Group (Fig. 2). A detailed stratigraphic study of this sequence at Hallett Cove, South Australia (Fig. 1), has identified turbidite and storm-dominated shallow marine facies¹². This section correlates very strongly with that of the fossil site.

The fossils reported here are preserved on an upper bedding-plane surface within basal sandstones of the Brachina Subgroup cropping out in Alligator Gorge of the Mount Remarkable National Park in the southern Flinders Ranges (Fig. 1). This sequence passes upward from massive sandstones which intertongue with dolomites of the Nuccaleena Formation, through interbedded shales and fine sandstones, into a thick medium-grained cross-bedded unit known as the ABC Range quartzite (Fig. 2). The upward coarsening and thickening Brachina Subgroup is interpreted to be the result of initial transgression followed by progradation into a sedimentary basin. Sedimentation took place in a storm- and tide-dominated shallow marine environment with an ENE slope into a deeper turbidite basin.

I do not propose to present a detailed taxonomic classification of the metazoan fossil. However, further investigation of the study area will hopefully result in the discovery of more specimens to help with systematics (the specimen has not been removed from the discovery site). The novel fossil may be interpreted as representing organisms which were basically foliate, leaf-shaped (frond) structures, with each preserved specimen lying on one of its two broad sides on a bedding plane within the sandstone. The frond-like structures consist of a

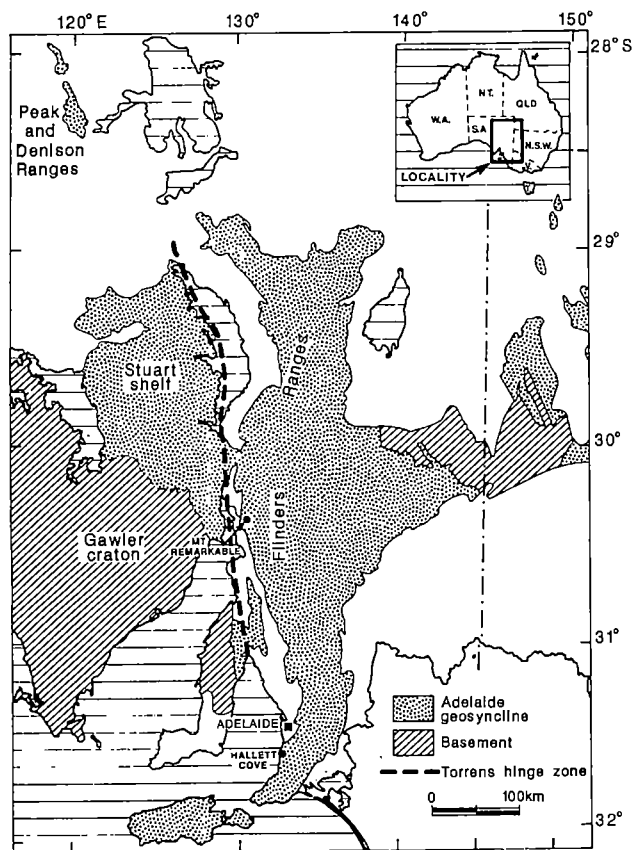

Fig. 1 Outcrop area of the late Proterozoic Adelaide geosyncline. Note the locality of the study area: Mount Remarkable in the southern Flinders Ranges.

relatively narrow median zone from which extend bilaterally opposed leaf-like branches. The specimens show regular spacing of branches, with specimen *b* (Fig. 3) displaying a wider spacing between consecutive branches. A number of incomplete individuals, preserved as impressions on a very thin shale parting in massive sandstone, are thought to have been oriented by rip or turbidity currents flowing in an ENE direction. The specimens overlap and show signs of distortion, making identification of individual outlines difficult. An incomplete frond (a in Fig. 3) is ~30 cm long and 6.5 cm wide, and is composed of about 30 partially or completely preserved branches extending from one side of a broad axial region. The median track is ~20 mm wide and tapers to a point at one end. Large areas of the branches show no systematic curvature, with each branch extending from the median track at an angle of 45°. Each branch is bounded by a well-defined groove. A more complete specimen (b in Fig. 3) clearly exhibits a narrower median track about which numerous lateral branches exhibit bilateral symmetry. The branches appear to extend opposite one another at an angle of 70–85° from the median track and are bounded by evenly spaced repetitive grooves. The specimen is 37 cm long and 9 cm wide.

Comparison of these specimens with those fossils from the Pound Subgroup representing sessile colonial *Cnidaria*¹ indicates that the metazoans of this latest discovery in the Flinders Ranges may belong to one of the two families Pteridiniidae Richter, 1955 and Charniidae Glaessner, 1979, as the fossils consist of a median track from which a leaf-like expansion extends with bilateral symmetry. Members of the former family are rare from the Flinders Ranges. These frond-like fossils of the Ediacara assemblage are considered to be allied to the living members of the Order Pennatulacea^{1,13}. Modern pennatulids (sea pens) are found growing vertically on sandy sea floors¹⁴ with their stalk moored to the substrate by a holdfast. Sea pens are found washed up on beaches, after being torn from their moorings by storm action. Fossils of the genus *Pteridinium*

Fig. 2 Stratigraphy of the late Precambrian Wilpena Group in southern Flinders Ranges. LST., limestone; FM., formation; QTZ., quartzite; SST., sandstone.

Gürich are known to occur in storm beds¹⁵. The median track of *Charniodiscus* Ford² extends downwards into a stalk which terminates in a basal attachment disk; lateral branches extend from the median track at an inclination of ~65–85° and bear foliate structures (polyp leaves) divided into ridges (polyp anthostoles). These secondary divisions that occur between the polyp anthostoles of the Charniidae, appear to be rare and minute in the family Pteridiniidae¹. In *Pteridinium*, three ribbed wings may extend from the axis¹⁶. *Pteridinium simplex* is characterized by its incised zig-zag median line and evenly spaced, repetitive lateral grooves which extend from the axis at ~70°. No stalks or attachment disks are known¹ for this species.

Strong similarities exist between the Brachina Subgroup fossils and *Pteridinium* found in the late Precambrian sedimentary units of the Nama Group of south-west Africa^{16–18}, the Valdai sediments of the White Sea coast of the USSR^{18–20}, the Carolina slate belt of the southeastern United States²¹, and the Pound Subgroup of the Ediacara Hills, South Australia^{13,22}. The Brachina Subgroup fossils are comparable in size and morphology to those of the Ediacara assemblage. There is no evidence of secondary grooving, as occurs between the anthostoles of the Charniidae, nor of any anchoring device, therefore I provisionally assign the fossils to the genus *Pteridinium* Gürich.

The Ediacara assemblage from the Pound Subgroup (Fig. 2) has been assigned a late Precambrian age^{1,3}, as have similar fossils from various localities around the world. The proposed Ediacaran Period^{5,23}, during which metazoans appear to have become diverse and relatively numerous, has been assigned to the interval 670–550 Myr⁴. In the present study area, the base of the Wilpena Group lies more than 3,000 m stratigraphically below the Ediacara Member of the Pound Subgroup (Fig. 2). The base of the Wonoka Formation (Fig. 2) has been suggested as the lower boundary of the Ediacaran in South Australia⁵. The first early metazoan assemblages were thought to appear at

Fig. 3 Photograph of the frond-like fossils preserved as impressions on thin shale parting in massive sandstone. Specimens *a* and *b* are described in the text. The coin, shown for scale, is 24 mm in diameter.

~640–620 Myr, and became diverse and frequent during the interval ~600–570 Myr. Ediacara assemblages should comprise almost by definition the first occurrences of metazoan body fossils^{1,4}. Radiometric dating suggests an age of 676 ± 204 Myr for the Brachina Subgroup west of the Flinders Ranges²⁴. The discovery of fossils in the Brachina Subgroup that are similar in size to those of the Ediacara assemblage, supports the placement of the lower boundary of the Ediacaran Period at the base of the Wilpena Group⁴. In addition, the fossils are the first unequivocal metazoan remains to be found in the Brachina Subgroup.

The discovery of metazoans in the Brachina Subgroup raises questions concerning radiometric ages and worldwide stratigraphic correlations. This sedimentary unit rests conformably on the Umberatana Group which marks the termination of late Proterozoic glaciation in the Adelaide geosyncline. An event which in several major regions pre-dates the first appearance of Metazoa is the last occurrence of Precambrian tillites¹. Such tillites overlain by Ediacara assemblages are known in Australia, south-west Africa, China, eastern Europe, Newfoundland, North Carolina and Sweden and may provide the potential for global lithological and biostratigraphical correlations. However, the recording of these various first appearances needs to be addressed further in stratigraphic and geochronometric terms.

Financial support was provided by the Flinders University research budget. I thank Bridget Youngs, Chris von der Borch and Alex Grady who initially reviewed the manuscript and provided many helpful comments. The figures were drafted by Gail Jackson, and Libby Eatts assisted with typing. Karin Sokoll and Alanah Sexton provided valuable field and research support respectively. I particularly thank Jim Gehling and Martin Glaessner for stimulating discussions during various stages of this work.

Blue light activates electrogenic ion pumping in guard cell protoplasts of *Vicia faba*

S. M. Assmann*, L. Simoncini† & J. I. Schroeder†

* Department of Biological Sciences, Stanford University, Stanford, California 94305, USA

† Department of Membrane Biophysics, Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, FRG

Transmembrane ion exchange and blue-light dependent responses are central processes in plants in general^{1,2} and stomatal guard cells in particular³. Stimuli, including light, cause H⁺ extrusion by stomatal guard cells^{4,5}, K⁺ uptake, osmotic swelling and enlarged stomatal pore apertures, resulting in increased leaf conductance for CO₂ influx and water efflux⁶. The mechanisms underlying ion movement and the specific response of stomata to blue light^{7–9} remain, however, unknown. We have now investigated these phenomena using gas-exchange techniques on leaves and whole-cell patch clamping^{10,11} of protoplasts. Blue light-stimulated stomatal opening in the leaf is correlated with activation of an electrogenic pump in the guard cell plasmalemma which results in hyperpolarizations as large as 45 mV and outward currents as large as 5.5 pA. The pump functions in the absence of K⁺; in the presence of K⁺ an increase in voltage noise upon light-induced hyperpolarization more negative than the K⁺ equilibrium potential implies K⁺ flow through K⁺-selective channels¹². The data are in accord with a chemiosmotic model of stomatal response¹³ whereby active H⁺ extrusion creates an electrochemical gradient for passive ion fluxes. A 25–35-s delay in the onset of hyperpolarization, and its peak several minutes after application of a blue light pulse suggest that blue light functions as an activator, rather than a direct energy source, for ion pumping.

Figure 1 shows a typical change in hydraulic conductivity, commonly referred to as 'stomatal conductance' of a leaf of *Vicia faba* L. (cv. long pod) following application of a transient blue light stimulus under a constant background illumination

Fig. 1 Transient increase in stomatal conductance in response to a 50-s pulse of $0.260 \text{ mmol m}^{-2} \text{ s}^{-1}$ incident blue light given under $0.525 \text{ mmol m}^{-2} \text{ s}^{-1}$ background red light. Note the absence of any increase in conductance following a 50-s pulse of $0.520 \text{ mmol m}^{-2} \text{ s}^{-1}$ red light applied in the same manner. Background red light was provided by a Sylvania 300W (PAR56/2MEL) lamp used in conjunction with a Kodak 1A red filter (50% cut-off at 645 nm) and a layer of No. 5A Cinemoid. Pulsed light was obtained by filtering light from a GE Gemini 300 projector lamp through a wideband hot mirror (OCLI, Santa Rosa, California) and a Roehm and Haas 2424 blue Plexiglass filter (maximum transmittance at 470 nm, half-bandwidth 100 nm) or a Corning 2-61 red glass filter. Stomatal conductance was measured using a null balance gas-exchange system³⁰. Conditions inside the gas-exchange cuvette were maintained at 23 °C, ambient CO_2 $300\text{--}250 \mu\text{l l}^{-1}$, vapour pressure deficit 0.75–0.95 kPa.

with high fluence rates of red light. As with *Commelina communis*¹⁴, a pulse of blue light results in a transient rise in stomatal conductance to water vapour which peaks ~20 min later. A red light pulse produces no increase in conductance (Fig. 1), demonstrating that the response stimulated by blue light is independent of both photosynthesis and the component of the stomatal response to light which is mediated by the guard cell chloroplasts¹⁵. The response can thus be attributed specifically to the action of the guard cell blue light photoreceptor⁷⁻⁹.

The high specificity provided by this dual-beam protocol^{8,14} was further utilized in an electrophysiological investigation of the membrane properties and ion fluxes underlying the blue light response of stomata. Studies using conventional electrophysiological techniques have shown hyperpolarization in response to white light^{16,17}. We used the whole cell patch-clamp technique^{10,11}, instead of intracellular recording, to ensure an unambiguous characterization of electrical responses of the plasmalemma as opposed to the tonoplast or a series combination of the two membranes¹⁸, thus solving a ubiquitous problem in plant electrophysiology. Patch clamping allowed us to observe either membrane potential (V_m) or membrane current, and to define solutions on both sides of the plasmalemma, so that gradients for passive ion fluxes could be manipulated or eliminated.

Seal formation on single guard cell protoplasts of *V. faba* L. (cv. long pod and grünehangdown) was facilitated by the presence of 1 mM CaCl_2 in the bath solution, by a pipette solution with an osmolality 10% less than that of the bath solution¹⁰, and by the use of Kimax glass (Kimble 34500) pipettes with tip resistances of 10–20 M Ω in symmetrical 150 mM KCl solutions¹⁹. Typical whole-cell membrane resistances were 1–5 G Ω , although resistances as high as 20 G Ω were observed. Immediately after the establishment of the whole-cell configuration, healthy cells exhibited a V_m of –20 to –50 mV which then declined towards 0 mV, presumably as a result of diffusional equilibration between the cell contents and the pipette solution. Cells typically stabilized at resting potentials of –10 to +10 mV.

In symmetrical 50 mM K^+ -glutamate solutions, a 30-s pulse of $0.050 \text{ mmol m}^{-2} \text{ s}^{-1}$ blue light given on a background of $0.500 \text{ mmol m}^{-2} \text{ s}^{-1}$ red light resulted in a transient membrane

Fig. 2 *a*, Transient membrane hyperpolarization in a guard cell protoplast in whole-cell recording mode, current clamp, in response to a 30-s pulse of $0.050 \text{ mmol m}^{-2} \text{ s}^{-1}$ blue light superimposed on a $0.500 \text{ mmol m}^{-2} \text{ s}^{-1}$ red light background. Incident fluence rates were measured above the air–water interface. Note the increase in voltage noise as the membrane hyperpolarized and the delay before the initiation of the response. Both external and pipette solutions contained 50 mM K^+ -glutamate, 5 mM MgCl_2 , 10 mM HEPES, 3 mM NaOH; internal solution contained in addition 9.2 mM (Na^+)₂-ATP in 20 mM Tris (final concentrations) and 100 μM EGTA. External solution was pH 7.15, 500 mosmol kg^{-1} ; internal solution was pH 7.4, 450 mosmol kg^{-1} . Osmolarities were measured in a vapour pressure osmometer (Wescor 5100c) and adjusted by the addition of D-mannitol. Temperature 22–24 °C. *b*, Membrane hyperpolarization in response to blue light. Solutions were the same as in *a* except that K^+ was replaced by the impermeant cation *n*-methylglucamine in both the external and pipette solutions, and the external solution contained 1 mM CaCl_2 . Note the relative absence of voltage noise. *a* and *b* show no response in dark-adapted cells on an initial exposure to the background red light; occasionally cells showed a transient hyperpolarization when the background light was turned on (not illustrated). The following conditions were identical for *a* and *b*. Background red light was obtained by placing a Kodak No. 29 gelatin (50% cut-off at 590 nm) and a Cinemoid No. 5A filter in the microscope light path (Zeiss 12V, 60-W 1251 bulb). Blue light was obtained by filtering light from a Liesegang Fantimat 150Af projector lamp through a Roehm and Haas 2424 blue Plexiglass filter. Control of membrane current and measurement of membrane potential were performed with an EPC-7 patch clamp (List Electronic) and recorded on a Racal store 4Ds tape recorder and a chart recorder. Protoplasts were obtained by modification of a published procedure³¹. Abaxial epidermal peels from six leaves of 3–6-week-old plants were incubated in 15 ml of 2% Cellulase Onozuka RS (Yakult Honsha Co.) and 0.022% Pectolyase Y-23 (Seishin Pharmaceutical Co.), 0.3 M D-mannitol and 1 mM CaCl_2 for 50–65 min in a shaking water bath (temperature 29–31 °C). Following passage through a 30- μm mesh, the enzyme solution was centrifuged at 125g for 12 min (Sigma 3E centrifuge) and the pellet, containing the guard cell protoplasts, was washed twice (125g for 8 min) in 0.5 M D-mannitol with 1 mM CaCl_2 and stored on ice in the same solution.

hyperpolarization peaking several minutes later (Fig. 2*a*). The characteristics of the hyperpolarization were similar to those of the stomatal response in the whole leaf (compare Figs 1 and 2) but had a faster time course, as might be expected of an early event in the phototransduction process occurring in an isolated system. Patch clamping allowed an accurate resolution of the initial kinetics of the response to blue light, revealing a 25–35-s delay between the onset of the blue light and the beginning of hyperpolarization. An identical delay was observed under longer illuminations with blue light (not illustrated), demonstrating that the onset of hyperpolarization is not correlated with termination of the blue light signal. Similar response kinetics were observed when the major permeant cation, K^+ , was replaced by the impermeant ion *n*-methylglucamine (Fig. 2*b*). In the absence of K^+ , the voltage noise of the response was greatly reduced, suggesting that this noise represents passive flux of K^+ through discrete channels¹² in response to the change in V_m . As in the intact leaf, no such response was observed to a pulse of red light ($n=7$, cf Fig. 3*a*), demonstrating that the responses illustrated in Fig. 2 are mediated by the blue light photosystem.

The blue light response was observed in cells that had resting potentials from –30 to +10 mV and within this range exhibited no apparent voltage dependence ($n=20$, not shown). No response to blue light was observed when ATP was eliminated

Fig. 3 *a*, Response of whole-cell membrane current to blue light. The membrane potential of the cell was voltage-clamped at $V_m = -4$ mV and the current response was low-pass-filtered at 10 Hz. Smaller current responses were also observed at this voltage (not illustrated). Solutions and illumination protocol were the same as in Fig. 2*b*. Note the absence of a response to a 30-s pulse of $0.050 \text{ mmol m}^{-2} \text{ s}^{-1}$ red light, obtained by transiently increasing the intensity of the microscope light. *b*, Same recording conditions as *a* except that the cell was voltage-clamped at -50 mV and the response was filtered at 60 Hz. Temperature 19°C . The response exceeds the zero current level (dashed line), indicating that blue light activates an outward current rather than an increase in membrane resistance.

from the pipette solution ($n = 7$, not shown). These observations led us to postulate that the hyperpolarization induced by blue light resulted from the activation of an electrogenic plasmamembrane ATPase. To test this hypothesis, the membrane potential was clamped at -50 mV, a potential more negative than the Nernst potential of all significant ionic species present in the external and internal solutions¹¹. The observation under these conditions of a blue light-stimulated outward current exceeding the zero current level (Fig. 3*b*) cannot be explained by passive ion fluxes, providing strong evidence for the operation of an electrogenic pump.

In the responses shown in Fig. 3, blue light induced outward currents as large as 5.5 pA . Given an average guard cell protoplast diameter of $14.1 \text{ } \mu\text{m}$ ($n = 20$), currents as large as $0.88 \text{ } \mu\text{A cm}^{-2}$ can be calculated. Previous observations of light-stimulated release of H^+ from guard cells^{4,5} suggest an electrogenic proton pump as the source of this current. Such a conclusion is further supported by the recent finding²⁰ that when suspensions of *V. faba* guard cell protoplasts illuminated with continuous high-intensity red light are exposed to a 30-s blue light pulse of the same fluence rate as that used in Figs 2 and 3, acidification of the medium occurs at rates comparable to the outward currents reported here.

In many types of plant cells²¹⁻²³, as well as in guard cells, H^+ extrusion appears to be coupled with K^+ uptake. The basis of that coupling is, however, unknown, available data being consistent with either an electrogenic H^+ pump or an antiporter with a stoichiometry for H^+ and K^+ which is not 1:1 (refs 24, 25). Our results showing electrogenic pumping in the absence of K^+ (Figs 2*b*, 3) clearly indicate that the electrogenic pump in guard cells which is activated by blue light is not an obligate K^+ antiporter. We conclude that the most likely mechanism underlying blue light stimulation of stomatal conductance to water vapour in the leaf (Fig. 1) is light activation of a hyperpolarizing proton pump in the guard cell plasmalemma which generates an electrical gradient for passive K^+ flux¹² driving increases in turgor. The data reported here therefore support a chemiosmotic model of stomatal opening¹³.

The results also have specific photobiological implications. The time course of the membrane hyperpolarization, particularly the delay between illumination onset and the initiation of hyperpolarization (Figs 2, 3), and the dependence of the response on ATP, are inconsistent with utilization of blue light as a source of photochemical energy for H^+ extrusion as occurs, for example, in *Halobacterium*²⁶. The response is observed when

guard cells are provided via the pipette solution with 9.2 mM ATP, a greater concentration than is typically measured in plant cells²⁷. Thus, it also seems unlikely that removal of an energy limitation on H^+ extrusion via blue light-induced enhancement of respiration²⁸ is occurring. Rather, blue light seems to function as a regulator of the electrogenic pump. Regulation could occur by a direct modulation of the membrane ATPase or by stimulation of redox reactions²⁹ that result in pump activation. Further application of the whole-cell patch-clamp technique to plant cells should prove valuable in elucidating the processes by which blue light and other environmental stimuli are transduced into cellular responses appropriate for plant function.

We thank Drs Eduardo Zeiger and Erwin Neher for use of equipment, comments on the manuscript and coordination of S.M.A.'s visit to the Department of Membrane Biophysics at the Max-Planck-Institut in Göttingen, where the patch-clamp experiments were performed. S.M.A. thanks also the members of the 1983 Cold Spring Harbor Single Channel Recording Course. This research was supported by a McKnight Fellowship to S.M.A. and Max-Planck stipendia to L.S. and J.I.S.

Protection of cottontop tamarins against Epstein-Barr virus-induced malignant lymphoma by a prototype subunit vaccine

M. A. Epstein, A. J. Morgan, S. Finerty, B. J. Randle & J. K. Kirkwood

Department of Pathology, University of Bristol Medical School, University Walk, Bristol BS8 1TD, UK

Epstein-Barr (EB) virus is one of the five herpesviruses of man. Strong links between this agent and the chain of events causing two human cancers, endemic Burkitt's lymphoma and undifferentiated nasopharyngeal carcinoma, have long been evident (reviewed in ref. 1). Because of this, and because of the very high incidence of nasopharyngeal carcinoma in certain large populations², it was suggested in 1976 that a vaccine should be developed against EB virus to prevent infection and thereby reduce tumour incidence amongst those at risk³. The virus-determined membrane antigen

(MA) was proposed as immunogen³ because it was known to elicit naturally occurring virus-neutralizing antibodies in man⁴⁻⁷ and because analogous antigens had been shown to act as effective experimental vaccines for preventing the herpesvirus-induced lymphomas of Marek's disease in chickens^{8,9}. Progress has been achieved in defining, quantifying and preparing MA molecules, and in enhancing their immunogenicity¹⁰; a sensitive assay for antibodies to MA has been elaborated¹¹. Here we report that isolated cell membranes expressing MA, or purified MA glycoprotein of relative molecular mass (M_r) 340,000 (gp340), have been used to vaccinate cottontop tamarins (*Saguinus oedipus*), and that animals receiving either preparation were protected against the effects of a 100% tumour-inducing challenge dose of EB virus.

The cottontop tamarin is the only species in which experimental EB virus infection regularly causes lesions¹² and recent investigations have established that these are true, clonally derived, malignant lymphomas¹³. Young adult tamarins from a successful breeding colony¹⁴⁻¹⁶ were used in the present studies.

For the membrane experiments, B95-9 cells grown as reported earlier¹⁷ and showing maximum expression of MA after treatment with tetradecanoyl phorbol acetate¹⁸, were disrupted and the plasma membranes collected by sucrose density gradient centrifugation¹⁹. The resulting material contained only trace amounts of infectious virus when titrated in fetal cord blood lymphocytes²⁰, several logs less than is necessary for infection. The purified membranes were injected intraperitoneally (i.p.) eight times into two tamarins at fortnightly intervals, each inoculation containing on average 2,500 units of MA gp340 as assessed by radioimmunoassay (RIA)¹⁷. Serological responses were measured by indirect immunofluorescence, a highly sensitive enzyme-linked immunosorbent assay (ELISA)¹¹, and standard virus neutralization tests which assess the ability of a given serum to prevent transformation by the virus of fetal cord blood lymphocytes^{7,20}; all neutralizations were repeated (up to three times) and included control sera of known titre, so as to take account of the inherent variations in sensitivity shown by cells from different cord bloods. Specific antibodies were rapidly

9	$10^{5.3}$	i.p.; i.m.	4/4

induced, eventually reached high titre, and were then powerfully virus-neutralizing; because the neutralization tests were all repeated more than once, neutralizing titres were recorded as being greater than the minimum obtained in each set of tests. The tamarins were considered to have been satisfactorily immunized when their levels of neutralizing antibody equalled or exceeded the highest titres found in sera from naturally infected human subjects.

The immunized animals were challenged with $10^{5.3}$ lymphocyte-transforming units of virus²⁰, a dose checked in advance for its ability to produce gross, multiple, malignant tumours within 21 days¹³ in 100% of unprotected tamarins (Table 1). The tumours presented as masses (not infiltrates) in spleen, liver, kidneys, gut wall and adrenals, and in numerous lymph nodes, causing enlargement from the normal 1-2-mm diameter up to 15-20 mm (ref. 13). Use of a 100% lymphoma-inducing challenge dose of virus was considered important for biological tests in a species where only small numbers of animals are available and inbred strains are unknown, but to ensure exclusion of equivocal results, two additional normal control

animals were also given the challenge material at the same time. The immunized tamarins remained entirely free of clinically detectable lesions whereas the normal control animals developed the expected gross multiple tumours within 2–3 weeks (Table 2).

Because it was known that purified MA gp340 prepared by a M_r -based method which conserved immunogenicity²¹ induced virus-neutralizing antibodies in various species when injected after incorporation in liposomes^{22,23}, we investigated the protective effects of these antibodies in tamarins, and the levels required for protection. In a pilot experiment, four animals were selected in whom differing amounts of neutralizing antibody were present after i.p. immunization with liposomal gp340, and all were then challenged with the 100% lymphomagenic dose of virus (Table 1). Table 3a shows that only the animal whose serum was strongly neutralizing was completely protected, whereas the other animals with much lower, or undetectable, levels of neutralizing antibody were not protected at all.

To confirm this result, two further tamarins were given gp340 in liposomes 17 times i.p. at fortnightly intervals, each dose containing on average 2,250 RIA units¹⁷. Antibodies were monitored as before and when these had reached high levels (Table 3b) the vaccinated animals were challenged with the 100% pathogenic dose of EB virus (Table 1), along with 2 normal control animals. The unprotected animals developed gross multiple tumours within 2–3 weeks whilst the vaccinated tamarins remained free of tumours (Table 3b); one protected animal exhibited minor transient swelling of a single inguinal lymph node draining the site of intramuscular (i.m.) injection in the thigh muscle, and the other developed similar inguinal node enlargement to 5 mm which rapidly regressed, accompanied by minor transient enlargement of a single mesenteric node.

These experiments demonstrate that gp340 prepared by the M_r -based method²¹ can be used as an efficient prototype subunit vaccine to protect susceptible experimental animals against tumour induction by a massive challenge dose of EB virus. The protected tamarins have remained well for more than 9 months and quite recent experiments with larger doses of gp340 have shown rapid induction of high-titre antibodies and followed the kinetics of their development²⁴. Investigation of the overall structure of the gp340 molecule has already indicated that more than 50% of its total mass is carbohydrate and that it is the protein component which is antigenic²⁵. The region of EB virus DNA carrying the gene for MA has been identified²⁶ and the nucleotide sequence of this gene is known²⁷; MA production by expression in pro- and eukaryotic cells therefore seems possible, and synthetic gp340 peptides could also be considered as immunogens, perhaps in combination with powerful new adjuvants²⁸. It should similarly be feasible to incorporate the MA gene into the genome of vaccinia virus to permit direct expression during vaccination with this agent^{29–31}. The present results establish a strong case for determined work in these directions to produce MA gp340 in a form suitable for use as a vaccine in humans.

Natural killer (NK) activity is mediated by a small population of peripheral blood cells that exhibit the homogeneous morphology of large granular lymphocytes (LGL)^{1–4}. In recent studies, human NK cell clones^{5,6} have been shown to contain a 200,000- M_r (relative molecular mass) protease-resistant chondroitin sulphate A proteoglycan, which has been localized to the secretory granule by X-ray dispersive analysis and by its resistance to cleavage by extracellular addition of chondroitinase AC or ABC (ref. 7). In the present study, we have used six different human NK cell clones to demonstrate that release of ³⁵S-proteoglycan correlates closely with cytolytic activity against various NK cell targets. When NK activity is blocked by monoclonal antibodies at either the effector cell level (LFA-1)⁸ or at the target cell level (TNK_{TAR})⁹, there is a concomitant decrease in exocytosis of proteoglycan. Monoclonal antibodies directed against recognition structures, for example anti-NK1a and anti-T3 (ref. 10), function as soluble stimuli, capable of initiating the release of ³⁵S-proteoglycan. Taken together, these results provide strong evidence for the stimulus-specific release of chondroitin sulphate A proteoglycans from NK cells when the cytolytic process is activated.

To determine whether chondroitin sulphate A proteoglycan was consistently released in the cytolytic mechanism of NK cells, we used six different human NK cell clones selected because of their ability to maintain stable cytolytic activity against a series of allogeneic target cells without previous immunization^{5,11}. Phenotypic analysis of these clones indicated that each expressed NKH1 antigen, a surface structure of 200,000- M_r associated with all NK cells in peripheral blood¹², and the T11/E rosette receptor. Clones JT3, CNK7 and CNK10 also expressed NKH2 antigen¹², while clone JT_B18 was NKH2 negative. Together, these four clones, which do not express the T3 antigen or T-cell receptor-like structures, represent the most common phenotypes of circulating NK cells^{2–4,12}. Clones JT9 and CNK8 bear NK1a, a T-cell receptor-like structure that is linked to surface T3 (ref. 10). Moreover, both clones are specific

Fig. 1 Comparison of natural cytotoxicity and proteoglycan release from NK clones (CNK7, JT3, CNK10, CNK8, JT_B18 and JT9) interacting with seven target cell lines (K562, REX, Molt-4, HL60, Laz 221, Daudi and KG-1).

Methods. Cytotoxicity experiments were performed in triplicate using V-bottomed microtitre plates. Medium for cytotoxicity assays was RPMI 1640 containing 5% pooled human AB serum and 1% penicillin-streptomycin. Assays were performed at an effector/target cell ratio of 10:1 using 5,000 ⁵¹Cr labelled target cells per well. Cytotoxicity was determined after 4 h of incubation at 37 °C by measuring release of ⁵¹Cr into the cell supernatant. Specific cytotoxicity was calculated according to a standard method¹¹. Simultaneously, duplicate cultures of the same cloned NK cells were used in proteoglycan release experiments. For the latter studies, NK cells were incubated with 100 µCi of ³⁵S-sulphate ml⁻¹ at concentrations of 2 × 10⁶ cells ml⁻¹ for 24 h at 37 °C. After ³⁵S-sulphate labelling, the cloned NK cells were centrifuged and washed twice to remove unincorporated ³⁵S-sulphate. ³⁵S-labelled NK cells (25,000) were incubated with 50,000 target cells (effector/target ratio of 0.5:1) in quadruplicate in V-bottomed microtitre plates for 4 h at 37 °C. Supernatants (150 µl) from two of the four wells were combined, resulting in duplicate 300-µl samples for analyses. Each 300-µl supernatant sample was applied, together with 25 µl of chondroitin sulphate carrier and 250 µl of 8 M guanidin hydrochloride (GnHCl), to separate PD-10 columns (1.5 × 5.5 cm) which were equilibrated and eluted under dissociative conditions of 4 M GnHCl, 0.1 M Tris-HCl, 0.1 M Na₂SO₄, pH 7.0. Eight 0.5-ml fractions were collected and after the addition of 0.5 ml ethanol and 12.5 ml Hydrofluor to each fraction, ³⁵S-radioactivity was quantitated using a β-scintillation counter. The total proteoglycan content (TPG) was determined by addition of 1% Nonidet p-40. Spontaneous release (SR) was obtained from labelled effector cells incubated with media in the absence of targets (8.5 ± 4.5%, mean ± s.d.). Stimulus-specific per cent proteoglycan (PG) release was calculated according to the following formula, in which experimental release (ER) is release occurring in the presence of a target cell: % specific PG release = (ER - SR) / (TPG - SR) × 100. To compare the proteoglycan release of various NK clones in experiments done on different days, we expressed the release of labelled proteoglycan as a percentage of the maximal proteoglycan release obtained with the optimal NK/target combination in a given experiment which included K562 three times, Molt-4 twice, and REX once. In the experiments shown, maximal release represented 46% of total proteoglycan content for the combination CNK7/REX, 36% for CNK10/Molt-4, 48% for JT_B18/K562, 12% for JT3/Molt-4, 52% for CNK8/K562 and 69% for JT9/K562.

for a 140,000-*M_r* surface antigen that is linked to cell activation and is identified by two monoclonal antibodies, anti-TNK_{TAR} (ref. 9) and 4F2 (refs 13, 14), which have been shown to block target cell killing by NK clones expressing the NKTa clonotype.

Cytotoxicity was determined by measuring ⁵¹Cr release into the cell supernatant after incubation of unlabelled effector cells with ⁵¹Cr-labelled target cells at a ratio of 10:1 at 37 °C for 4 h¹¹. Release of ³⁵S-proteoglycan into the cell supernatant was determined during incubation of ³⁵S-labelled effector cells with unlabelled target cells at a ratio of 0.5:1 for 4 h at 37 °C. To compare proteoglycan release by different targets with toxicity against these cells, the maximum release of ³⁵S-proteoglycan from each NK clone in a given experiment was considered to represent 100% release and all other release values were expressed as a per cent of maximal release. As shown in Fig. 1, specific cytotoxicity closely paralleled proteoglycan release; this was found for T3-positive (T3⁺) as well as for T3-negative (T3⁻) NK clones. Figure 2 summarizes the results of 34 experiments using six different NK clones and seven different targets; there was a linear relationship between percentage cytotoxicity and percentage maximal proteoglycan release (correlation coefficient 0.81).

The specific exocytosis of ³⁵S-proteoglycan was also evaluated in conditions in which NK cytotoxicity was inhibited at either the effector cell or target cell level. Monoclonal antibody 2F12, which is specific for LFA-1 antigen^{15,16} and is known to block cytotoxicity of NK clones at the effector cell level⁸, inhibited cytotoxicity of both T3⁺ and T3⁻ NK clones, with the greatest inhibition occurring with Molt-4, CEM and REX targets (Fig. 3). Reductions in exocytosis of ³⁵S-proteoglycans closely paralleled the inhibition of cytotoxicity. The monoclonal antibody anti-TNK_{TAR} inhibited the NK cytotoxicity at the target cell level of the T3⁺ clones JT9 and CNK8, both of which express the NKTa clonotype (Fig. 3). In these experiments, specific release of proteoglycans from JT9 and CNK8 was also markedly reduced, whereas there was no change in either cytolytic function or release of proteoglycans from clones JT_B18 and JT3. The correlation coefficient between percentage maximal

proteoglycan release and percentage cytotoxicity for all experiments shown in Fig. 3 was calculated to be 0.92.

Release of proteoglycans from NK cell clones was also evaluated under conditions known to trigger activation of NK cells without the presence of target cells. The results (Table 1) demonstrate that binding of monoclonal anti-T3 and anti-NKTA antibodies was effective in triggering release of ³⁵S-proteoglycans from NK cell clones JT9 and CNK8 but not from JT_B18 and JT3. The former two clones, but not the latter two, are known to use a T-cell receptor-like complex in expressing their cytolytic function¹⁷. Monoclonal anti-T6, which was used as a negative control antibody, did not initiate any exocytosis of proteoglycan. In contrast, the lectins concanavalin A (Con A) and Phytohaemagglutinin (PHA) were able to trigger release of proteoglycan from all NK clones regardless of differences in cell surface phenotype, with PHA being more effective than Con A. Control experiments using these monoclonal antibodies showed that the viability of the cells before and after triggering by trypan blue exclusion was never less than 95% and that the lactate dehydrogenase release into the cell supernatant was never greater than 5%.

The data presented here provide strong evidence that proteoglycan exocytosis occurs concomitantly with stimulus-specific

Fig. 2 Correlation of per cent specific cytotoxicity with per cent maximal proteoglycan release for 34 different experiments. $r = 0.81$.

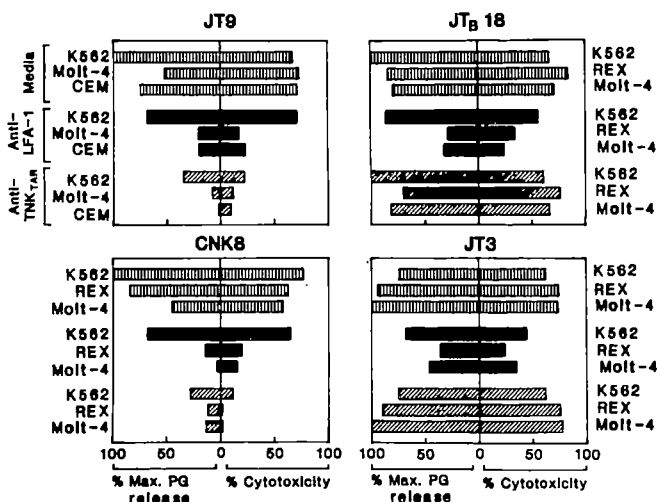

Fig. 3 Natural cytotoxicity and proteoglycan release are inhibited by anti-LFA-1 and anti-TNK_{TAR} antibodies, which exert their blocking activity through epitopes on the NK and target cells, respectively. Either effector cells or target cells were incubated with media (▨) or monoclonal antibody anti-LFA-1 (■) or anti-TNK_{TAR} (▤) for 30 min at room temperature before the assay, and both specific cytotoxicity and per cent maximal proteoglycan release were measured as described in Fig. 1 legend, except that cytotoxicity experiments were performed using an effector/target cell ratio of 5:1. Maximal proteoglycan release was 65% of total proteoglycan content for the combination JT9/K562, 46% for CNK8/K562, 46% for JTB18/K562 and 13% for JT3/Molt-4.

activation of the cytolytic capacity of NK cells. In a companion study of cloned NK cells, ³⁵S-proteoglycan was demonstrated to be localized in intracellular granules by X-ray dispersive analysis and was shown to be a protease-resistant chondroitin sulphate A proteoglycan⁷. By using a panel of six human NK cell clones and a variety of different target cells, we now also demonstrate a linear correlation between specific cytotoxicity and release of proteoglycan (Figs 1, 2), indicating that this secretory granule constituent is specifically released during the NK cytolytic process. This conclusion is further supported by the demonstration that blocking of NK activity by monoclonal antibodies anti-LFA-1 and anti-TNK_{TAR}, which inhibit cytotoxicity at the effector cell and target cell level, respectively, also concurrently inhibit the release of intracellular proteoglycans (Fig. 3). In addition, triggering of NK clones with soluble agonists through specific receptors or through binding of Con A and PHA similarly resulted in the release of radiolabelled proteoglycans (Table 1).

Protease-resistant chondroitin sulphate A proteoglycan may function as a carrier for cytolytic proteins or may protect the NK cell from injury by the cytotoxic molecules which are released during the lethal reaction^{18,19}. The results presented define the secretory nature of the NK cellular response in terms of a secretory granule marker, intracellular proteoglycan, and are compatible with the stimulus-specific nature of target cell cytotoxicity.

Table 1 ³⁵S-Proteoglycan release by NK clones activated with soluble stimuli

NK clone	Anti-T6	Anti-T3	Anti-NKTA	Con A	PHA
JTB18	0	0	0	17	26
JT3	0	0	0	7	63
JT9	0	25	28	20	59
CNK8	0	46	40	14	29

Values are per cent total proteoglycan release from various cloned NK cells incubated for 4 h with monoclonal antibodies anti-T6 (control), anti-T3 and anti-NKTA, or the lectins PHA (20 µg ml⁻¹) and Con A (20 µg ml⁻¹). Proteoglycan release was determined as described in Fig. 1 legend.

A *trans*-acting class II regulatory gene unlinked to the MHC controls expression of HLA class II genes

C. de Prével, B. Lisowska-Grospierre*, M. Loche, C. Griscelli* & B. Mach

Department of Microbiology, University of Geneva School of Medicine, CH-1211, Geneva 4, Switzerland, and Unité d'Immunologie Pédiatrique, INSERM U 132, Hôpital des Enfants Malades, Paris Cedex, France

Class II (or Ia) antigens are highly polymorphic surface molecules which are essential for the cellular interactions involved in the immune response. In man, these antigens are encoded by a complex multigene family which is located in the major histocompatibility complex (MHC) and which comprises up to 12 distinct α - and β -chain genes, coding for the HLA-DR, -DQ and -DP antigens^{1,2}. One form of congenital severe combined immunodeficiency (SCID) in man, which is generally lethal, is characterized by an absence of HLA-DR histocompatibility antigens on peripheral blood lymphocytes (HLA class II-deficient SCID). In these patients, as reported here, we have observed an absence of messenger RNA for the α - and β -chains of HLA-DR, -DQ and -DP, indicating a global defect in the expression of all class II genes. Moreover, the lack of expression of HLA class II mRNAs could not be corrected by γ -interferon, an inducer of class II gene expression in normal cells. Family studies have established that the genetic defect does not segregate with the MHC. We conclude, therefore, that the expression of the entire family of class II genes is normally controlled by a *trans*-acting class II regulatory gene which is unlinked to the MHC and which is affected in the patients. This gene controls a function or a product necessary for the action of γ -interferon on class II genes.

The expression of the entire class II multigene family is restricted to a limited number of cell types, is strictly regulated developmentally, and is coordinately induced by soluble mediators (such as γ -interferon). Cells from class II-deficient SCID cases could thus provide a model for the study of the regulation of this gene family. In these patients, the absence of expression of class II antigens on lymphocytes and macrophages³ explains the immunological unresponsiveness

Fig. 1 Northern blot analysis of mRNAs from PHA-stimulated blasts of HLA class II-deficient SCID patients (lanes 1-3) and of a normal healthy donor (C).

Methods. RNA preparation and Northern blot analysis were performed as reported elsewhere²⁰. Briefly, total RNA from PHA-blasts was prepared by the guanidinium thiocyanate-caesium chloride procedure, denatured in glyoxal and electrophoresed in a 1.8% agarose gel (20 g per slot). RNA was transferred to diazobenzylmethyl paper, and the filters were hybridized in 50% formamide, 0.75 M NaCl, 10% dextran sulphate at 42°C, with nick-translated ³²P-cDNA probes (specific activity 1.5–3 × 10⁸ c.p.m. g⁻¹). The final washes were done under stringent conditions: 0.1 × SSC buffer, 68°C, twice for 30 min each before autoradiography. The following ³²P-labelled probes were used: DRα⁵, DRβ and DQβ⁶, DPβ⁷, invariant chain (II)⁸, and class I heavy-chain pHLA 44/2 (CI.1; ref. 21). Some blots were dehybridized in 99% formamide, 5 mM Tris-HCl pH 7.5, 1 mM EDTA, 65°C, three times for 10 min each, and rehybridized. The specific probe used for each of the six experiments is indicated. The films were exposed for 4 days; prolonged exposure (17 days) gave identical results (data not shown). RNAs from fresh peripheral blood lymphocytes from one patient gave identical results.

Fig. 2 Segregation of HLA haplotypes in two families. Open symbols, healthy individuals; solid symbols, HLA class II-deficient SCID patient; ●, ■, deceased individuals. **A**, The healthy twins and their affected brother are haplo-identical with respect to HLA. Haplotypes: *a* = A2 B12; *b* = Aw32 B40; *c* = A1 B21; *d* = Aw32 B8. **B**, The two immunodeficient siblings do not have any HLA haplotypes in common. Haplotypes: *a* = A26 B35 DR2; *b* = A19.2 B35 DR3; *c* = A19.2 B7 DR1; *d* = A3 B7.

Fig. 3 Northern blot analysis of lymphocyte mRNA from HLA class II-deficient SCID patients (lanes labelled 1) and a healthy donor (C) following *in vitro* stimulation with γ -interferon. The probes used were: **A**, DRβ; **B**, CI.1.

Methods. Blood lymphocytes from patient 1 and from a healthy donor were cultured for 48 h in RPMI 1640 medium, 10% fetal calf serum, in the presence of recombinant interferon (500 U ml⁻¹), provided by Biogen SA. RNA preparation and Northern blot analysis were performed as described in Fig. 1 legend. The blot in **A** was first hybridized with DRβ cDNA⁶; the final washes were performed in 0.5 × SSC buffer at 65°C. (In these conditions, the DRβ ³²P-labelled cDNA also hybridizes to DQβ and DPβ mRNAs.) This blot was dehybridized and rehybridized with an HLA class I ³²P-cDNA probe, CI.1 (ref. 20).

and the dramatic clinical course, which results frequently in death. In 12 patients with HLA class II-deficient SCID, we had observed an absence of HLA-DR molecules on peripheral blood lymphocytes, even after stimulation with phytohaemagglutinin (PHA)⁴. Other cells of the body that are normally HLA-DR-positive were also totally negative. In three of the patients, we have studied the expression of the different genes of the entire *HLA-D* region, using specific HLA class II α- and β-chain complementary DNA probes, described previously⁵⁻⁷.

Messenger RNA for HLA-DR, -DC and -SB antigens (α- or β-chains) could be easily detected in blood lymphocytes from normal individuals. In contrast, no class II mRNA was found in samples of stimulated lymphocytes from patients with HLA class II-deficient SCID (Fig. 1), even after prolonged exposure of the autoradiographs. This block in mRNA expression concerns the three subregions *HLA-DR*, *-DQ* and *-DP*. However, a normal amount of mRNA for the HLA-DR-associated invariant chain (II)⁸ was observed. This difference is of interest in view of the general coupling of expression of the *Ii* gene with that of HLA class II genes both in specific tissues and following induction with γ -interferon^{9,10}. RNA for HLA class I antigens either was present in a normal amount or was somewhat decreased.

SCID seems to be inherited as an autosomal recessive trait, with a high rate of consanguinity and a high frequency of families with two or more affected children of both sexes^{3,4}. As the defect of class II expression concerns not only bone marrow-derived cells, but also all cells that can express class II antigens in normal individuals, we are dealing with a germline defect which consists of a global inability to express HLA class II genes in the form of mRNA. The defect is not only global in terms of all the cell types involved, but it is also multigenic and involves each of the multiple α- and β-chain genes within the *HLA-D* region. Individual mutations in each of these genes are unlikely and massive deletions have been ruled out as a possible explanation by the finding of a normal restriction pattern for *DR* and *DC* genes by Southern blot hybridization¹¹. Cells from one class II-deficient SCID patient were found to revert to a HLA-DR-positive phenotype after 3–5 weeks in Epstein-Barr virus-induced culture⁴. Another argument for the structural integrity of class II genes in these patients comes from an analysis of the family pedigree, including the HLA typing of the parents and relatives. Figure 2A shows a family in which two children are haplo-identical for the MHC, yet one is healthy and the other is affected. Figure 2B illustrates another family in which two siblings are non-identical with respect to the MHC, yet both are affected. Therefore, it can be concluded that the genetic defect which results in a block of class II gene expression does not segregate with the MHC. To our knowledge, no animal model with such a mutation has yet been described.

γ -Interferon is known to stimulate the expression of class II genes, even in cells that do not normally express them^{9,10}. However, the lack of expression of class II genes in HLA class II-deficient SCID could not be corrected by γ -interferon. Figure 3 shows the result of an analysis of RNA from lymphocytes

Fig. 4 A class II regulatory gene maps outside the major histocompatibility complex. This gene, or its product, is a potential target for γ -interferon (see text).

from a patient and from a normal control, following incubation in the presence and absence of γ -interferon. The unresponsiveness to interferon of the class II genes contrasts with the response of class I genes (Fig. 3), indicating that the cells from the immunodeficient individuals possess the γ -interferon receptor and are capable of responding.

In these SCID patients, therefore, the class II structural genes are intact and the defect in their expression is caused by a mutation(s) in a gene located outside the MHC. Thus, a trans-acting gene unlinked to the MHC is involved in the normal regulation of the expression of the class II multigene family (Fig. 4). The exact mechanism of this regulation could be transcriptional or post-transcriptional. In this regard, it is of interest that all class II genes of man and mouse (α - and β -genes) share two short sequences 5' upstream of the genes, referred to as 'class II boxes'^{12,13}. From the unresponsiveness of class II-deficient SCID cases to γ -interferon, it is also evident that the induction of class II gene expression observed with γ -interferon in normal cells requires the normal functioning of the class II regulatory gene. The target for the effect of γ -interferon could be the regulatory gene itself, or its product. The expression of the invariant chain gene, although induced by γ -interferon, is probably not under the control of the same regulatory gene.

It is possible that the DR-negative variants^{14,15} in which we had also observed an absence of class II mRNA with the presence of mRNA for class I and invariant chains^{16,17}, represent an analogous situation. Interestingly, fusion with a DR-positive B cell has resulted in the re-expression of the DR antigen of the variant type¹⁸. It has also been shown that fusion of a human DR-positive line with several mouse Ia-negative lines resulted in a DR-negative phenotype, even when the human MHC was still present in the hybrid cells¹⁹. The latter observation is also compatible with the existence of a class II regulatory gene, which would be lost in most of these fusions. Finally, the model presented in Fig. 4 can also accommodate a class II regulation of a negative kind (analogous to the repressors of prokaryotes) in which induction of class II genes would normally result from the inhibition of a negative signal.

The study of HLA class II-deficient patients has thus provided evidence for a novel gene controlling the expression of Ia antigens. One can anticipate that, in the future, this gene may be isolated and transfected into bone marrow stem cells of immunodeficient patients in order to achieve somatic correction of the disease.

A role for N_i in the hormonal stimulation of adenylate cyclase

Richard A. Cerione*, Claudia Staniszewski*, Marc G. Caron*, Robert J. Lefkowitz*, Juan Codina† & Lutz Birnbaumer†

† Department of Cell Biology, Baylor College of Medicine, Houston, Texas 77030, USA

The best understood system for transduction of extracellular messages into intracellular signals is the hormone receptor-coupled adenylate cyclase. In such systems receptors are functionally coupled to the enzyme by two special proteins, termed the stimulatory and inhibitory guanine nucleotide regulatory proteins (N_s and N_i , respectively). These proteins, thought to mediate, respectively, stimulatory and inhibitory influences on the adenylate cyclase, are members of a larger class of heterotrimeric guanine nucleotide regulatory proteins involved in membrane signal transduction¹⁻⁵. We have studied the interactions of the various components of the adenylate cyclase system by co-reconstituting pure β -adrenergic receptors, pure N_s and N_i , and functionally resolved preparations of the catalyst in phospholipid vesicles. In the absence of N_i , β -adrenergic receptor/ N_s -mediated catecholamine stimulation of the enzyme is relatively modest (~1.3-fold). Surprisingly, however, when N_i is also present, stimulation increases dramatically (up to 7-8-fold) because of a greater suppression of basal relative to agonist-stimulated enzyme activity. Thus, N_i may actually be required for maximal agonist stimulation as well as for inhibition of the adenylate cyclase.

It is believed that hormonal stimulation of the adenylate cyclase (C) system is a simple vectorial signal transduction process whereby the receptor first facilitates the activation of N_s by GTP and the GTP/ N_s complex then activates adenylate cyclase. The stimulation process is terminated by the GTPase activity of N_s . Recently, we reported that the co-insertion into phospholipid vesicles of the pure guinea pig lung β -adrenergic receptor (β AR), with the pure human erythrocyte N_i protein and a resolved bovine caudate adenylate cyclase preparation (that is, resolved from β AR and N_s by Sepharose-6B chromatography) indeed results in the establishment of a modest responsiveness of adenylate cyclase activity to isoprenaline⁶. The results of Fig. 1 confirm this observation. For the conditions shown in Fig. 1 the maximal stimulation by isoprenaline never exceeds two fold and in some cases is nearly non-existent. The average (fold) stimulation by isoprenaline in 11 such experiments is 1.32 ± 0.07 (mean \pm s.e.m.). It seems likely that the modest effect of isoprenaline in these three component systems reflects, at least in part, the effective activation of N_i molecules by GTP alone, thus resulting in a significant basal level of cyclic AMP production.

Fig. 1 The effect of N_i on β -adrenergic-mediated adenylate cyclase activity in phospholipid vesicles. The data are presented as the means of triplicate determinations, with the ranges denoted by error bars.

Methods. Resolved bovine caudate adenylate cyclase (C) preparations (150 μ l; see below), 1.14 μ g of human erythrocyte N_s (≈ 12 pmol), 12 pmol of guinea pig lung β -adrenergic receptor (β AR) and 1.8 μ g of human erythrocyte N_i (≈ 19 mol) were inserted into phospholipid vesicles as follows. Soybean phosphatidylcholine (0.1 ml of a 17 mg ml⁻¹ sonicated solution; Sigma) was incubated with the adenylate cyclase preparation (0.15 ml), 0.08–0.12 ml of 100 mM NaCl, 10 mM Tris-HCl pH 7.4 and 25 μ l of octyl glucoside (17%) for 20–30 min on ice. At this point the nucleotide regulatory proteins (30 μ l of N_s , 36 μ l of N_i) and the receptor [40 μ l of β AR which had been preincubated with 10 μ l of alprenolol (5 μ M) and 10 μ l of bovine serum albumin (BSA, 50 mg ml⁻¹)] were added to the lipid solutions, which had been incubated for ~1–2 min at 4 °C. Rhodopsin (195 pmol) was also included in the incubations containing N_i as we had found previously that rhodopsin promotes the maximal activation of this regulatory protein¹¹. However, under the conditions described for these experiments, N_i alone is effectively activated and essentially identical results are obtained in the absence of rhodopsin. These incubation mixtures were then immediately applied (at 4 °C) to Extracti-gel columns (1 ml of gel) pretreated with 4 vol. of 100 mM NaCl, 10 mM Tris-HCl pH 7.4 containing 2 mg ml⁻¹ of BSA, then equilibrated with 100 mM NaCl, 10 mM Tris-HCl pH 7.4. The protein-vesicles, in the column eluate, were then pelleted using polyethylene glycol essentially as described previously¹¹. The resultant protein-lipid pellets were resuspended in 75 mM Tris-HCl pH 7.8, 1 mM dithiothreitol (DTT, final volume 0.35 ml) and 20 μ l of the vesicles were assayed for adenylate cyclase activity as described below. The β -adrenergic receptor was purified ($\geq 95\%$) from guinea pig lung membranes as described previously¹⁶. The pure receptor preparations were concentrated to ~300 pmol ml⁻¹ using an Amicon concentration cell with a YM 30 membrane, and then stored at -90 °C in 50 mM Tris-HCl, 50 mM NaCl, 0.2% digitonin pH 7.4. N_s and N_i were purified ($>90\%$) as described by Codina *et al.*¹² and stored at -90 °C in 10 mM HEPES pH 8.0, 1 mM EDTA, 20 mM β -mercaptoethanol, 30% ethylene glycol, 150 mM NaCl, 50 μ g ml⁻¹ BSA and in 1.65–10% Lubrol PX. The catalytic moiety (C) of adenylate cyclase was solubilized from bovine caudate nucleus with sodium cholate and isolated from the other components of the system by Sepharose-6B chromatography as described elsewhere^{6,17}. These preparations were stored in 50 mM Tris-HCl, 200 mM sucrose, 1 mM DTT, 15 mM MgCl₂, 3.5 mg ml⁻¹ crude soybean phosphatidylcholine and 0.6% sodium cholate, pH 7.6. The concentrations of β AR are expressed in terms of [¹²⁵I]-iodocyanopindolol binding activity. The amounts of N_s and N_i are expressed in terms of total protein as described previously¹²; the molar concentrations of these proteins were determined assuming a relative molecular mass of 95,000 (ref. 12). The adenylate cyclase assays were performed in a total volume of 0.1 ml containing 50 mM Na-HEPES pH 8.0, 1 mM EDTA, 0.25 mM ATP, 3 mM phosphoenolpyruvate, 10 μ g ml⁻¹ pyruvate kinase, 0.1 mg ml⁻¹ BSA, 0.1 mM cyclic AMP (cAMP), 10 μ g ml⁻¹ myokinase, 2 μ Ci of [³²P]ATP and 2 mM MgCl₂. Isoprenaline (Iso) = 0.1 mM; GTP = 10 μ M.

The construction of a vesicle system comprised of pure β AR, pure N_s , resolved adenylate cyclase and pure human erythrocyte N_i results in three striking effects (Fig. 1): (1) the absolute levels of adenylate cyclase activity are reduced (relative to β AR/ N_s /C vesicles) both when assayed in the absence and in the presence of isoprenaline; (2) the reduction of activity in the absence of isoprenaline is much more marked than in its presence; and due to this, (3) the relative stimulation of adenylate cyclase activity by isoprenaline ('fold stimulation') is increased. In the case shown in Fig. 1, the stimulation of adenylate cyclase activity by isoprenaline is 1.8-fold in the β AR/ N_s /C vesicles and increases

to 7-fold in the β AR/ N_s / N_i /C vesicles. In a series of 11 experiments the 'fold' stimulation of the enzyme by isoprenaline was 1.32 ± 0.07 in the absence and 3.61 ± 0.6 in the presence of N_i . We have documented that the effects of N_i in the reconstituted system were not the result of preferential reduction of the basal (GTP) activities due to a reduced incorporation of adenylate cyclase or N_s , or of any change in the efficiency of β AR reconstitution (data not shown).

Figure 2a demonstrates clearly that the ability of N_i to increase the relative stimulation of adenylate cyclase activity by isoprenaline is a dose-dependent phenomenon. At the highest level of N_i incorporated, the adenylate cyclase activity assayed in the absence of isoprenaline was inhibited by ~85%, while activity measured in the presence of isoprenaline was inhibited by ~42% (Fig. 2b); this results in an increase in the stimulation of adenylate cyclase activity by isoprenaline from ~1.1-fold for control vesicles, to 4.1-fold in vesicles containing N_i . The mean inhibitions of basal and isoprenaline-stimulated activities by N_i were, respectively, $76 \pm 3\%$ and $43 \pm 4\%$ ($n = 11$). In a separate series of experiments using the resolved subunits of N_i or transducin, we have found that the activities of N_i described here are essentially properties of the $\beta\gamma$ - rather than the α -subunit (manuscript in preparation).

Our results indicate a dual role for the inhibitory nucleotide binding regulatory protein (N_i) of the adenylate cyclase system, one being the mediation of inhibition of adenylate cyclase activity, the other being a tightening of the coupling between adenylate cyclase activity and stimulatory hormones by the marked attenuation of the basal (N_s -mediated) adenylate cyclase activity.

Moreover, not only do our results suggest a dual role for N_i , they also imply two distinct functions for the stimulatory hormone/receptor complex. The first is to accelerate the actual activation of N_s . The second is to suppress the inhibitory action of N_i on GTP-activated N_s . Evidence for the first function derives from studies in which it has been shown that β -agonists promote the interaction between the pure β AR and N_s in phospholipid vesicles, leading to increases in the rate of GTP γ S binding to N_s and the turnover number for the GTPase activity^{7–11}. Evidence for the second function of the hormone/receptor complex is provided by the present work, which indicates that addition of agonists to vesicles containing β AR/ N_s / N_i /C markedly relieves the N_i inhibition, leading to a significant increase in hormonal stimulation.

Of further interest is the fact that purification studies have indicated that in native membranes there is 4–10 times more N_i than N_s (ref. 12), this agrees well with the relative ratios of N_i / N_s (4–5 times) required in our reconstitution systems to both inhibit GTP-activated N_s and enhance the relative stimulation by hormone.

The specific mechanisms by which N_s and N_i are activated under physiological conditions (that is, in the presence of stimulatory and inhibitory receptors, GTP and in a lipid milieu) still remain to be delineated. Both N_s and N_i are heterotrimeric in structure ($\alpha\beta\gamma$) and in detergent solution their activation by non-hydrolysable analogues of GTP involves subunit dissociation into α_s (ref. 13) or α_i (ref. 14), and an intact $\beta\gamma$ species J.C., J. D. Hildebrandt & L.B., unpublished results. It has been suggested that it is the α_s /guanine nucleotide complex which stimulates adenylate cyclase activity. However, the mechanism by which inhibition occurs has been a more controversial subject. It has been suggested that it is the generation of $\beta\gamma$ following N_i activation (and dissociation) which effectively complexes activated α_s (refs 1, 14), while other studies in N_s -deficient S49 *cyc*⁻ cells suggest a direct inhibitory action of α_i on adenylate cyclase¹⁵. Recent studies using phospholipid vesicle systems similar to those described here indicate that bovine brain N_i or bovine retinal transducin inhibit the N_s -stimulated adenylate cyclase rather than the intrinsic activity of the enzyme itself¹⁹. Moreover, experiments using the isolated subunits of these proteins indicate that the $\beta\gamma$ subunit complex is primarily

Fig. 2 *a*, Effect of varying N_i on the stimulation (fold) by isoprenaline of the adenylate cyclase activity in phospholipid vesicles. Resolved bovine caudate adenylate cyclase (C) preparations (150 μ l), human erythrocyte N_i (1.16 μ g = 12 pmol), human erythrocyte N_i (0.63 μ g, 1.27 μ g, 3.82 μ g = 6.6 pmol, 13.4 pmol, 40.2 pmol, respectively) and 12 pmol guinea pig lung β AR were added to reconstitution incubations and protein-lipid vesicles were then formed and isolated as described in Fig. 1 legend. The isolated vesicles were resuspended in 0.38 ml of 75 mM Tris-HCl pH 7.8, 1 mM DTT and assayed (20 μ l) for adenylate cyclase activity (30 min at 30 $^{\circ}$ C) as described in Fig. 1 legend. Isoprenaline (Iso) = 20 μ M, GTP = 0.1 mM. The amount of N_i incorporated into the lipid vesicles was determined by assaying 35 S-GTP γ S binding as described previously¹¹. *b*, Effect of varying N_i on the total adenylate cyclase activity in phospholipid vesicles. The experimental conditions were as described for *a*. *c*, Effect of varying N_i on the incorporation of the β -adrenergic receptor into phospholipid vesicles. Experimental conditions as for *a*. The amount of β AR incorporated into the lipid vesicles was determined by 125 I-iodocyanopindolol (125 I-CYP) binding as described previously¹⁸.

involved in mediating the inhibition of GTP- (or isoprenaline plus GTP)-stimulated adenylate cyclase (manuscript in preparation). This would then suggest that a hormone/receptor-mediated release of the system from inhibition by N_i , as documented here, would be due to the complex between hormone/receptor and activated α_s /GTP becoming insensitive to the inhibitory action of $\beta\gamma$.

We thank Lynn Tilley for her diligence and patience during the preparation of this manuscript, and Drs Allen Spiegel and Robert Somers for the preparation of rhodopsin.

Regulation of the association of membrane skeletal protein 4.1 with glycophorin by a polyphosphoinositide

Richard A. Anderson & Vincent T. Marchesi

Department of Pathology, Yale University School of Medicine, 310 Cedar Street, PO Box 3333 New Haven, Connecticut 06510, USA

Many of the physical properties of the erythrocyte membrane appear to depend on the membrane skeleton, which is attached to the membrane through associations with transmembrane proteins¹⁻⁵. A membrane skeletal protein, protein 4.1, is pivotal in the assembly of the membrane skeleton because of its ability to promote associations between spectrin and actin⁵⁻⁹. Protein 4.1 also binds to the membrane through at least two sites: a high-affinity site on the glycophorins^{2,10} and a site of lower affinity associated with band 3 (ref. 11). The glycophorin-protein 4.1 association has been proposed to be involved in maintenance of cell shape^{2,12,13}. Here we show that the association between glycophorin and protein 4.1 is regulated by a polyphosphoinositide cofactor. This observation suggests a mechanism which may explain the recently reported dependence of red cell shape on the level of polyphosphoinositides in the membrane¹⁴⁻¹⁶.

Purified glycophorin, unlike many transmembrane proteins, is soluble in aqueous buffers in the absence of detergents, forming a micellar structure consisting of 14-18 glycophorin monomers with a sedimentation coefficient in the range 7-8S¹⁷. The micellar form of glycophorin varies in its residual intrinsic phospholipid content depending on isolation conditions^{18,22}, but retains the ability to bind protein 4.1. The interaction between micellar glycophorin and protein 4.1 is highly specific and can be used as a method for affinity purification of protein 4.1 (our unpublished results).

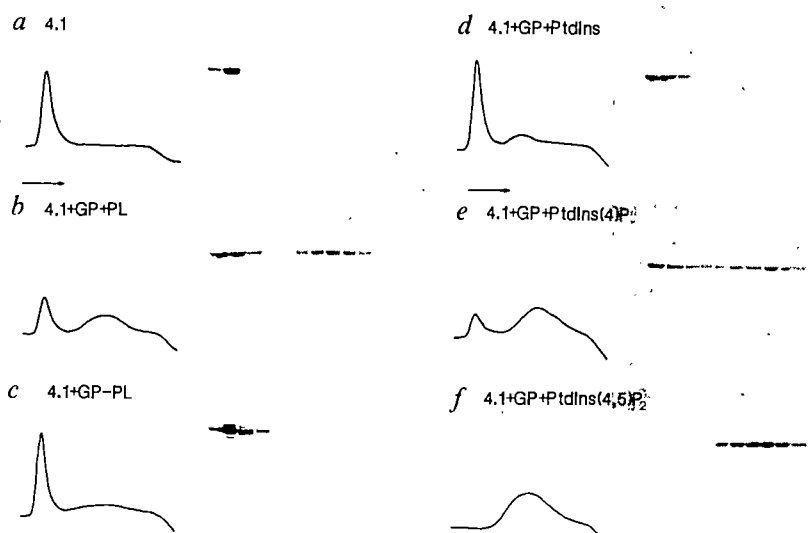

Because of the large size of the glycophorin micelles, the complexes of protein 4.1 and micellar glycophorin could be separated easily from free protein 4.1 by density gradient centrifugation. Micellar glycophorin which retained intrinsic bound phospholipid specifically associated with protein 4.1 (Fig. 1*b*), but this ability was lost on extraction of the bound intrinsic phospholipid (Fig. 1*c*). To demonstrate that extraction of bound phospholipid did not irreversibly denature glycophorin, the extracted phospholipids were recombined with glycophorin; glycophorin reconstituted in this way regained its protein 4.1 binding activity, whereas glycophorin treated identically but without added intrinsic phospholipid, did not bind protein 4.1 (not shown).

To determine whether the association between glycophorin and protein 4.1 required a specific phospholipid, glycophorin free of phospholipid was reconstituted with various phospholipids and its protein 4.1 binding capacity studied. Although all the phospholipids were readily reconstituted into glycophorin micelles, only the polyphosphoinositides restored the ability of glycophorin to bind protein 4.1 (Table 1 and Fig. 1*d-f*). Glycophorin forms a stable mixed micelle with phospholipids, probably by hydrophobic interactions between the acyl chains of the phospholipid and the transmembrane segment of glycophorin. The stability of this complex is demonstrated in Fig. 2*a*, in which glycophorin micelles containing 32 P-labelled polyphosphoinositides were analysed by density gradient sedimentation. The polyphosphoinositides completely co-migrate with glycophorin, indicating that the complex is quite stable. Furthermore, on addition of protein 4.1 the sedimentation coefficient of the glycophorin-polyphosphoinositide micelle increases demonstrating formation of a ternary complex. The polyphosphoinositides show a differential reconstitution of glycophorin's protein 4.1 binding activity (Fig. 1*e, f*). Glycophorin micelles containing phosphatidylinositol 4-phosphate

Fig. 1 Sucrose density gradient analysis of the association of protein 4.1 with glycophorin-phospholipid micelles showing absorbance at 280 nm and corresponding fractions on SDS-polyacrylamide gel electrophoresis (SDS-PAGE). *a*, Protein 4.1 alone; *b*, protein 4.1 plus glycophorin containing intrinsic phospholipid; *c*, protein 4.1 plus glycophorin stripped of phospholipid; *d*, protein 4.1 plus glycophorin reconstituted with phosphatidylinositol (PtdIns); *e*, protein 4.1 plus glycophorin reconstituted with PtdIns(4)P; *f*, protein 4.1 plus glycophorin reconstituted with PtdIns(4,5)P₂. The glycophorin in *c* was treated as in *d-f*, but without added phospholipid.

Methods. Glycophorin was prepared by the lithium diiodosacrylate/phenol method¹⁸, stripped of phospholipid by extraction with chloroform/methanol/12M HCl (200:199:1)²², and desialated². Desialoglycophorin was reconstituted with phospholipids by addition of aliquots of glycophorin (5 mg ml⁻¹) in 60 mM octyl- β -D-glucoside to a dry phospholipid film. The detergent was removed by dialysis, leaving a solution of glycophorin-phospholipid mixed micelles^{2,27}.

The phospholipid content of glycophorin micelles was quantitated by phosphate analysis^{49,50}. Protein was measured by the method of Lowry using bovine serum albumin as a standard^{2,51}. Purified protein 4.1 (refs 5, 24) and or glycophorin at a 1:2 molar stoichiometry was applied to a 5–20% sucrose density gradient. The gradients were centrifuged at 40,000 r.p.m. for 16 h in a Beckman SW-40 rotor. The buffer comprised (in mM); 130 KCl, 20 NaCl, 10 Tris, 1 MgCl₂, 0.5 β -mercaptoethanol, 0.1 diisopropylfluorophosphate, pH 7.6 (isotonic KCl buffer).

(PtdIns(4)P) bound protein 4.1 with lower apparent affinity than micelles containing phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂). The association between protein 4.1 and glycophorin-PtdIns(4,5)P₂ was abolished by treatment of protein 4.1, with *N*-ethylmaleimide, demonstrating that the binding is specific (not shown).

To determine whether the glycophorin-polyphosphoinositide complex could be a binding site for protein 4.1 on the red cell membrane, we measured the ability of different glycophorin-phospholipid combinations to compete with membranes for

contrast to the results obtained with glycophorin micelles reconstituted with other phospholipids (Table 1). Glycophorin-PtdIns(4,5)P₂ micelles displaced ³²P-protein 4.1 from IOVs more effectively than micelles containing PtdIns(4)P. A plot of the data using the method of Dixon²⁶ indicated that the inhibition of protein 4.1 binding to IOVs is competitive (not shown). Glycophorin-polyphosphoinositide micelles did not block protein 4.1 binding by direct interactions with the membrane, as IOVs did not bind glycophorin-polyphosphoinositide micelles and there was no measurable exchange of ³²P-polyphosphoinositide between micellar glycophorin and the stripped IOVs.

The glycophorin-polyphosphoinositide micelle contains a specific, high-affinity binding site for protein 4.1 which competes with membranes for protein 4.1 binding. To show that glycophorin in a membrane environment also requires the polyphosphoinositides as cofactors for protein 4.1 binding, glycophorin was reconstituted into phosphatidylcholine liposomes together with other phospholipids^{2,27}. We also prepared phosphatidylcholine liposomes containing polyphosphoinositides but no glycophorin, to determine whether protein 4.1 associates directly with the polyphosphoinositides. ³²P-labelled protein 4.1 bound saturably and with high affinity ($K_a > 10^7$ M⁻¹) to phosphatidylcholine liposomes containing glycophorin and PtdIns(4,5)P₂. In contrast, liposomes containing glycophorin and other phospholipids showed only nonspecific protein 4.1 binding. Phosphatidylcholine liposomes containing only PtdIns(4,5)P₂ bound protein 4.1 with low affinity ($K_a < 10^5$ M⁻¹).

The association of protein 4.1 with liposomes containing glycophorin and PtdIns(4,5)P₂ indicates that the phospholipid requirement of glycophorin in the membrane is highly specific for PtdIns(4,5)P₂, which suggests that this complex is a protein 4.1 binding site on membranes. However, if this is the case liposomes containing glycophorin-PtdIns(4,5)P₂ should compete with IOVs for protein 4.1 binding. To study such competition, liposomes were combined with IOVs and competition for ³²P-protein 4.1 binding was measured after separation of IOVs and liposomes by sedimentation through a sucrose cushion (see Fig. 3 legend). In these conditions the liposomes remain in the supernatant whereas the IOVs sediment and are found in the pellet. Analysis of the supernatant and the pellet showed that liposomes containing glycophorin were uniformly separated from IOVs (Fig. 3a) and that protein 4.1 binding to IOVs was

Table 1 Effect of phospholipid reconstitution of micellar glycophorin on inhibition of protein 4.1 binding to stripped IOVs

Phospholipid reconstituted	Concentration of glycophorin (μ g ml ⁻¹) at 50% inhibition of 4.1 binding	Moles of phospholipid/glycophorin*
PtdIns(4,5)P ₂	51	1.11
PtdIns(4)P	115	1.05
Phosphatidylinositol	>400	0.98
Phosphatidic acid	230	0.95
Phosphatidylserine	360	1.05
Phosphatidylethanolamine	>400	0.90
Phosphatidylcholine	>400	0.95
No lipid	>400	0.02

* Mean of three determinations of phospholipid, by phosphate assay^{49,50}, and protein, by Lowry's assay^{2,51}.

protein 4.1 binding. Inside-out erythrocyte membrane vesicles (IOVs) depleted of protein 4.1 were prepared^{23–25} and reconstituted with trace amounts of ³²P-labelled protein 4.1. The ³²P-protein 4.1 appeared to retain complete membrane-binding activity, as over 90% of the labelled protein bound to IOVs or glycophorin micelles and competed with unlabelled protein 4.1 for binding.

Micellar glycophorin containing PtdIns(4,5)P₂ or PtdIns(4)P inhibited protein 4.1 binding to stripped IOVs (Fig. 2b), in

Fig. 2 *a*, Sedimentation profiles of ^{32}P -protein 4.1 (○), glycoprotein reconstituted with ^{32}P -PtdIns(4,5) P_2 (△), and complexes of protein 4.1 and glycoprotein that had been reconstituted with ^{32}P -PtdIns(4,5) P_2 (▲) and ^{32}P -PtdIns(4)P (●). *b*, Inhibition of protein 4.1 binding to stripped IOVs by different glycoprotein-phospholipid mixtures: ●, glycoprotein stripped of phospholipid; △, glycoprotein-PtdIns; ○, glycoprotein-PtdIns(4)P; ▲, glycoprotein-PtdIns(4,5) P_2 ; ■, glycoprotein with intrinsic phospholipid. **Methods.** *a*, Protein 4.1 and polyphosphoinositides were labelled endogenously in IOVs with [γ - ^{32}P]ATP 52 . The polyphosphoinositides were extracted from membranes with chloroform/methanol/12 M HCl(100:200:1), and the ^{32}P -labelled PtdIns(4)P and PtdIns(4,5) P_2 were purified on a neomycin B-glycophase G CPG/200 column 53 . The purity of the polyphosphoinositides was analysed by TLC 53 . *b*, Protein 4.1 binding to stripped IOVs and inhibition of binding were determined in isotonic KCl buffer. ^{32}P -labelled protein 4.1 (3.5 μg) was combined with stripped IOV (60 μg of protein) then glycoprotein was added and the suspension was incubated for 1 h at 4 °C, then sedimented at 30,000g (30 min) through a 10% sucrose cushion to separate free 4.1 from bound 4.1. The concentration of glycoprotein in the IOVs was estimated from the sialic acid content of the IOVs 2 .

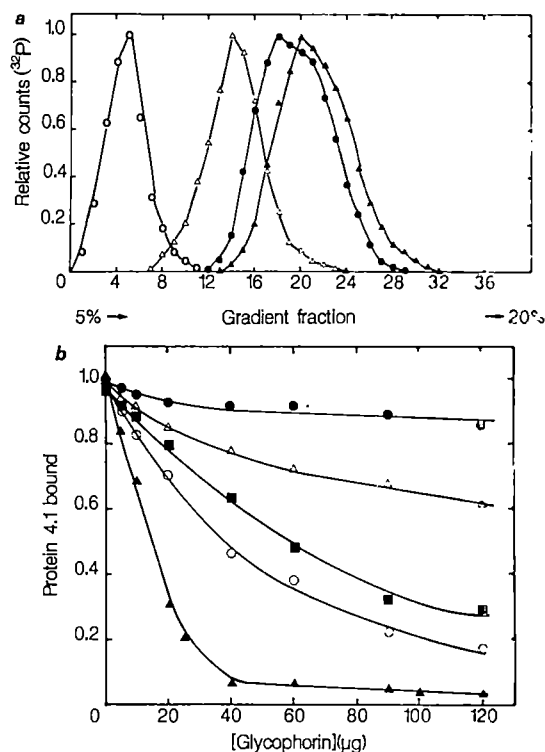

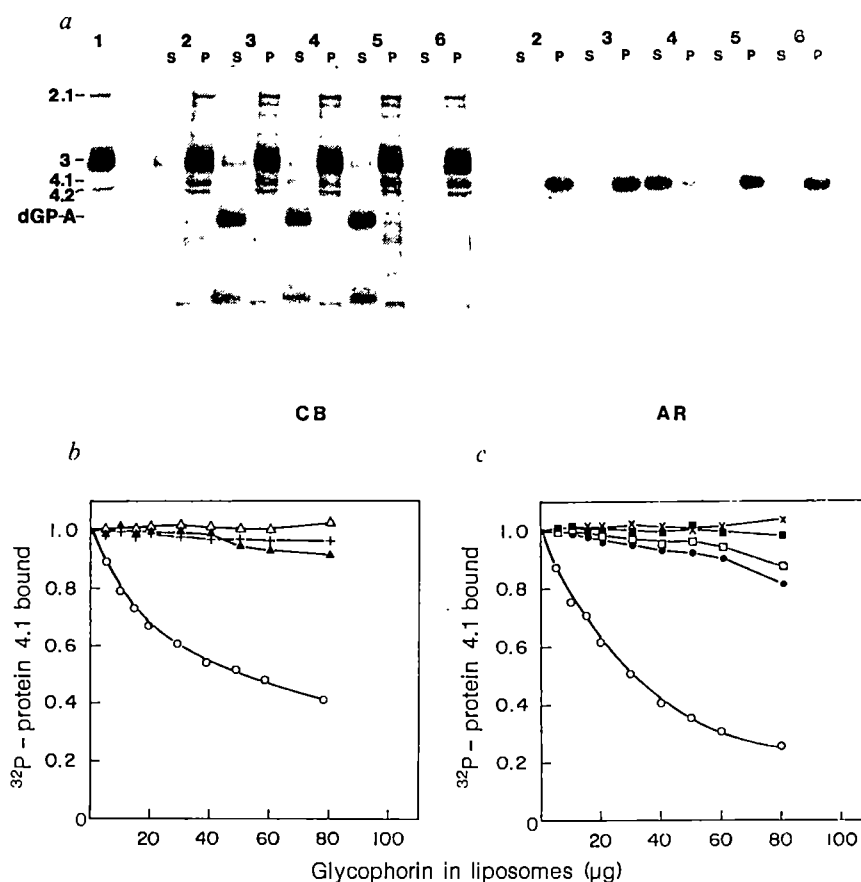

Fig. 3 Inhibition of ^{32}P -protein 4.1 binding to stripped IOVs by phosphatidylcholine liposomes containing glycoprotein, additional phospholipids, or glycoprotein and additional phospholipids. *a*, 7–15% SDS-PAGE (CB, Coomassie blue-stained; AR, corresponding autoradiogram) of supernatants and pellets from a qualitative experiment, showing inhibition of ^{32}P -protein 4.1 binding to stripped IOVs. Lane 1, stripped IOVs; lanes 2, supernatant (S) and pellet (P) of ^{32}P -protein 4.1 bound to stripped IOVs; lanes 3, as lanes 2 except that liposomes containing desialoglycoprotein (dGP) were added to IOVs (the glycoprotein was pre-stripped of all phospholipid before reconstitution into liposomes); lanes 4, as lanes 2 except that liposomes containing dGP and PtdIns(4,5) P_2 were added to IOVs; lanes 5, as lanes 2 except that liposomes containing dGP and PtdIns(4)P were added to IOVs; lanes 6, as lanes 2 except that liposomes containing PtdIns(4,5) P_2 alone were added to IOVs. *b*, Quantitative inhibition of ^{32}P -protein 4.1 binding to stripped IOVs by phosphatidylcholine liposomes containing: dGP alone (+), dGP and PtdIns(4)P (▲), dGP and PtdIns(4,5) P_2 (○), and PtdIns(4,5) P_2 alone (△). *c*, Same as *b*, but phosphatidylcholine liposomes contain: PtdIns(4,5) P_2 and PtdIns(4)P (×); dGP and phosphatidylinositol (■); sGP and phosphatidylserine (□); dGP and phosphatidic acid (●); dGP, PtdIns(4,5) P_2 and PtdIns(4)P (○). **Methods.** Phosphatidylcholine liposomes were prepared by the detergent dialysis method using octyl- β -D-glucoside 2,27 . Phosphatidylcholine (30 mM), desialoglycoprotein (0.12 mM), other different phospholipids at various concentrations, and octyl- β -D-glucoside (340 mM) were combined in an argon atmosphere, then extensively dialysed (5–6 days) against isotonic KCl buffer flushed with argon 2 . After dialysis the liposomes were layered on a 5–20% sucrose density gradient and centrifuged for 22 h at 200,000g in a Beckman SW-40 rotor. Liposomes containing glycoprotein float at 6–7% sucrose whereas free glycoprotein sediments to the bottom of the gradient. The liposome fraction was collected, dialysed against isotonic KCl, and sedimented at 150,000g for 20 min to concentrate and select for larger liposomes. The molar ratio of phosphatidylcholine (PC) to glycoprotein in the liposome after dialysis was 690 ± 90 mole PC per mole dGP as determined by phosphate 50 and protein 51 analysis. The mol% of added phospholipid to phosphatidylcholine before dialysis was: 0.9 for PtdIns(4,5) P_2 , 1.8 for PtdIns(4)P, 3 for phosphatidic acid, 19 for phosphatidylserine, and 10 for other phospholipids. Stripped IOVs (35 μg of protein) were recombined with 1.2 μg of ^{32}P -protein 4.1 (30,000 c.p.m. μg^{-1}). When quantitating the competitive binding of ^{32}P -protein 4.1 between IOVs and liposomes, IOVs with bound ^{32}P -protein 4.1 were combined with liposomes, incubated for 90 min at 23 °C, layered over a 10% sucrose cushion, and centrifuged at 38,000 g for 30 min. In these conditions IOVs sediment through the sucrose cushion whereas liposomes float at the interface of the cushion. When using liposomes lacking glycoprotein in the binding inhibition assay, the same amount of phospholipid was used as in liposomes containing glycoprotein.

inhibited only by liposomes containing both glycophorin and PtdIns(4,5)P₂ (Fig. 3a-c). Furthermore, quantitation of the competition of ³²P-protein 4.1 binding to IOVs demonstrated that liposomes must contain both glycophorin and PtdIns(4,5)P₂ before they can compete for protein 4.1 binding with IOVs (Fig. 3b, c). Liposomes containing glycophorin as well as other phospholipids did not compete with IOVs for protein 4.1 binding. The fact that liposomes containing up to 19 mol% phosphatidylserine (PS) did not compete with IOVs for protein 4.1 binding demonstrates that the association between protein 4.1 and membranes containing PS²⁸ is of lower affinity than that of the protein 4.1-glycophorin association. Interestingly, liposomes containing glycophorin and both PtdIns(4,5)P₂ and PtdIns(4)P are more effective competitors of protein 4.1 binding to IOVs than liposomes containing glycophorin and PtdIns(4,5)P₂ (Fig. 3c). This result suggests that while PtdIns(4)P by itself does not promote glycophorin-protein 4.1 interactions in the membrane, it may have a synergistic effect on the association of protein 4.1 with glycophorin-PtdIns(4,5)P₂.

Thus, the association between protein 4.1 and the glycophorins appears to be regulated by the polyphosphoinositides. While neither glycophorin nor the polyphosphoinositides bind protein 4.1 in the absence of the other, the association of PtdIns(4,5)P₂ with the cytoplasmic domain of glycophorin forms a high-affinity membrane binding site for protein 4.1. The concentration of the polyphosphoinositides in the membrane is maintained by kinases and phosphatases which are specific for each of the *myo*-inositol phosphate monoesters^{7,29-31}. The red cell also has a membrane-bound Ca²⁺-activated phospholipase C which is highly specific for the polyphosphoinositides³²⁻³⁴. The concentrations of PtdIns(4,5)P₂ in the red cell membrane decreases when the cellular ATP concentration falls, or when the Ca²⁺ concentration increases; in both conditions the cell membrane undergoes striking physical changes^{12,15,32,33}. Many hypotheses have been proposed to account for this correlation^{12,15,34,35}; the data presented here provide yet another possible mechanism.

A reduction in the concentration of PtdIns(4,5)P₂ available for binding to the cytoplasmic domain of glycophorin could lead to the release of protein 4.1 from its glycophorin binding site, and hence to its relocation within the cell, possibly binding to band 3 (ref. 11). Indeed, a decrease in the concentration of the polyphosphoinositides as a consequence of metabolic depletion or increased cytoplasmic Ca²⁺ concentration resulted in a dramatic decrease in the ability of stripped IOVs to bind protein 4.1 (our unpublished results).

An exciting implication of this finding is an expansion of the role that the polyphosphoinositides may have in cellular regulation. In most cells the polyphosphoinositides are cleaved by phospholipase C in response to stimulation by extracellular ligands that bind to transmembrane receptors. Cleavage of the polyphosphoinositides results in the release of inositol 1,4,5-trisphosphate and 1,2-diacylglycerol, both of which may act as second messengers^{29-31,36-38}. However, an alteration of the membrane levels of the polyphosphoinositides may also affect the interaction of membrane proteins with other proteins or enzymes, possibly modifying their intracellular biological activities. In this manner, the polyphosphoinositides may play a more versatile part as membrane-bound phosphorylated cofactors. So far, the only example of this potential regulatory role is the interaction of protein 4.1 with glycophorin. However, analogues of protein 4.1 are found in most cells³⁹⁻⁴⁶. In the brain, the protein 4.1 analogue appears to be synapsin I⁴⁵, a protein which is associated with synaptic vesicles and may play a part in the release of neural transmitters^{47,48}. If synapsin I retains functional as well as structural similarity to protein 4.1, the polyphosphoinositides may also have a key role in the interaction of synapsin I with the synaptic vesicles.

Erratum

Flow law for ice in polar sheets

W. S. B. Paterson; Reply by C. S. M. Doake & E. W. Wolff
Nature **318**, 82-83 (1985)

AN error in *Nature*'s editorial office led to the use of an uncorrected proof for W. S. B. Paterson's contribution to this Matters Arising item. In line 5, the word 'constant' should read 'parameter'. The first sentence in paragraph 3 should read '(2) At Camp Century, the strain rate measured for $\tau_{xz} = 10$ kPa, where x and z define a regular coordinate system, is less than the observational error⁴.' In the address, the postcode should read 'Canada VOP 1HO'.

Geneva meeting the best expected

Only the most unrestrained optimists expected written agreement last week between the United States and the Soviet Union on arms control. It is sufficient that there is to be another meeting.

UNREASONABLE optimism, far from being reprehensible, is more often one of the engines of beneficent change. How else could the New World, encompassing the United States, have been discovered? But unreasonable optimism is an encumbrance when its consequences include unreasonable disappointment, of which there has been far too much in the week following the meeting at Geneva between President Ronald Reagan and Mr Mikhail Gorbachev, general secretary of the Communist Party of the Soviet Union. The fact is that, since high summer, there has not been the slightest chance that the two men in person, however friendly they chose to be, would cut through the difficulties that have defeated their diplomats over several months. The chance that Geneva would bring a specific agreement on strategic arms control had shrunk to nothing by mid-September, and for reasons that had become generally understood. The best that could be hoped for is that the two meeting at Geneva would agree to meet again (see *Nature* 14 November, p.91). In reality, they have done twice as well as that, and have agreed to meet again in 1986 and 1987. It would have been a bad business for all of us if this had not come about. So it is reprehensible that so many newspapers and other sources of public comment should be saying that nothing happened at Geneva. That the two sides did not fall out is what happened.

Where things go from here is the absorbing question. The statements at the end of the Geneva meeting are fuller and emptier than might have been expected. The two superpowers have gone out of their way, with the review conference of the Non-Proliferation Treaty successfully just behind them, to reaffirm their opposition to the spread of nuclear weapons, but have not explicitly said that they will honour, let alone strengthen, the Anti-Ballistic Missile Treaty, the properly ratified agreement on arms control threatened by some of the statements in favour of anti-ballistic missile defences put out from the United States in recent months. Similarly, nothing was said about what will happen when the SALT II treaty (unratified) expires at the end of the year; presumably the calculation is that this question is subsumed in the declaration that the permanent negotiators on arms control at Geneva should accelerate their search for an agreement on strategic arms. Meanwhile, the Soviet side makes no secret of its distaste for US plans for the Strategic Defense Initiative, while the United States can claim some credit for having been allowed to stand firm.

What, then, will happen next? The most urgent task to be tackled once the negotiators reassemble at Geneva is that they should trim their sails to what their leaders say they have agreed. The goal seems to be a 50 per cent reduction of strategic arms, but it is not clear whether the count is to be made by launchers or by warheads. The difference is easily bridgeable, but could also easily be magnified into an insuperable obstacle. The two leaders, having made their journey to Geneva and having claimed success, have a continuing responsibility to ensure not merely that their negotiators are suitably flexible but that the people not privy to the negotiations, the rest of us, are reassured from time to time by public rehearsals of what the understanding is supposed to have been. Otherwise, especially in openly warring Washington, there is a risk that the objective will be corrupted or misunderstood.

Meanwhile, there is a strong case for paying more explicit

attention to the softer parts of the Geneva agreement, those in which the participants promised fuller cooperation on a variety of issues, cultural and scientific exchanges prominent among them. Such aspirations are commonplace when statesmen meet and have little else to agree about. The backroom boys can afterwards be asked to say what scientific collaboration means, and can draw up more detailed agreements for signature at later meetings. The process is almost a formality. Grave officials of learned academies settle on new numbers to describe what numbers of man-months of reciprocal visits shall be allowed on either side. Lists of priorities are drawn up specifying what each side would like to learn from the other, but with the reservation that nothing sensitive in the military sense should be included. Then, when everything is signed and sealed, it turns out that one side or the other is unable or unwilling to make the agreement work. In the past decade or so, for example, it has usually been impossible for Western academies to fill their quota of man-months allowed in the Soviet Union. It is a step in the right direction that, on this occasion, the United States and the Soviet Union have specified, vaguely it must be acknowledged, thermonuclear fusion as a field in which collaboration might be worthwhile. But, yet again, they have been putting the cart before the horse.

The reality is that the formal agreements reached between academies of countries otherwise hostile to each other are never satisfactory. What is needed in the dealings between the United States and the Soviet Union on scientific collaboration is not a set of quotas and a list of priorities but a mechanism by which scholars in both places can decide for themselves what kinds of collaborative research they would like to undertake. Thus the Soviet Union should (and probably does) know that there are many people in the West who would give their eye teeth to work at some Soviet archaeological site, or have a chance to tackle some geological investigation in the Soviet Union. It goes without saying that there are different fields of science in the United States in which Soviet scientists are eager to participate. The obvious difficulties — that both sides are sensitive about security — are well understood, and could be more explicitly defined. Why not, within such a framework, agree that there should be a pot of money to facilitate exchanges and then agree that the projects on which it is spent should be determined by those directly involved, not by their governments' civil servants? To follow past patterns is to invite failure and, ultimately, to bring science into disrepute unfairly. □

Unity by common fright

Europe's plan to collaborate in high technology seems to have struck a welcoming chord.

EUROPE seems to have made an unexpected discovery about itself. When the government of France issued its rallying call to the rest of Europe that there should be a collaborative programme of technological research and development, it was natural that other governments in Western Europe should be suspicious of the motives. For one thing, France did not hide its belief that such a programme was a necessary counterweight to the US Strategic Defense Initiative (SDI), which cannot but be a power-

ful means of stimulating high technology in the United States; the snag was that many governments had good reasons for not opting out of SDI. But, equally, there was no way of making sure that the plan called Eureka was not another way of advancing French claims to European leadership in technology, or perhaps even a way of persuading other governments to contribute to French advancement. For why else, the sceptics were asking earlier in the year, has France been urging technical collaboration on the rest of Europe at least since 1968, when M. Pierre Aigrain (then in the French government, now a director of the French Thomson company) tried on his government's behalf to persuade the European Communities to joint action? During M. François Mitterrand's presidency, the exhortations to technical collaboration have been even more frequent and insistent.

The surprise is that other governments in Western Europe seem at last to have taken to listening to what the French are saying. After two decades of scepticism, the belief that France may have been right all along has begun to gain ground. So much, at least, appears to have been the impression they created at the ministerial meeting on Eureka held at Hannover earlier this month. What seems to have happened in this economically disappointing year is that Western Europe has become collectively despondent about its technical future. Most governments are trying hard to succeed in high technology; most of them are presented every other day with evidence of how difficult it is to succeed in the face of competition from Japan and the United States. It is not surprising that one participant at Hannover said that European governments are now "running scared".

So, almost by chance, Mitterrand's Eureka will succeed when his and his predecessors' efforts in the same direction have mostly failed. The French president deserves credit for his persistence, the other governments of Western Europe for their new-found realism. But it is one thing to be agreed on a common cause and quite another to be sure of attaining it. The practical question still to be answered is whether mechanisms can be found that will enable Eureka to deliver the prizes its supporters promise. Two features of Eureka have so far been agreed. The framework of collaboration will be wider than the European Communities as such, so as to include Austria, Sweden and Switzerland in particular. And the programme will be supported not by another huge pot of public money, but by the funds of those most likely to benefit, the companies that decide to engage in transnational projects with each other.

On the face of things, it is not obvious why European companies should not collaborate with each other on worthwhile technical projects without France's banner labelled Eureka. Although the European Communities have regulations to prevent anti-competitive collusion by competing companies, these are neither as explicit as in the United States, nor are the penalties of transgression as fearsome. Part of the explanation for the poverty of international collaboration in Europe in past decades must surely be the conservatism of even progressive European industrial companies, many of whom still consider themselves as bitter rivals for the same block of overseas trade, that with the United States in particular. There is a chance that exhortation by itself may change this state of affairs, in which case Eureka may be very cheap. More probably, there are technical projects yet to be devised where public money will help to oil rusty wheels.

European governments should also recognize that the kind of collaboration foreseen by Eureka cannot be the basis of long-term economic success. It may help, in the short run, if more companies collaborate on the development of improved products, but either the agreements will then lapse and the companies will revert to rivalry, or they will find they have a successful product which they can market successfully only through some commonly owned channel, perhaps even an independent company in its own right. They will also discover, on the way to success of that kind, that the most wholehearted collaboration cannot succeed if the products whose development is intended are not sold competitively. The lesson from Japan on this point is clear; Japanese companies have succeeded in the export of

high-quality technological products only because their domestic market is even more demanding than those abroad. So will European governments follow the logic of the enterprise on which they have engaged in Eureka, and agree that success entails the banishment of restrictive practices on public purchasing; of the regulations and unwritten rules by which governments in Europe try to preserve the national identity of their domiciled companies; and of the barriers that persist to the free movement of academics and their students from one part of Europe to another? Unless governments agree that these impediments to efficiency are long-term barriers to success in high technology, Eureka will fail. □

Honest pennies to earn

Britain's environment research council should count again the costs of success.

THE British Natural Environment Research Council may fear that there is no way in which it can win friends, or placate its critics, but there is an awkward contradiction built into the way it is compelled to operate on a shrinking public budget. The framework of the inconsistency dates to the Rothschild reorganization of British civil science in 1971, but the issue has been sharpened only in the past five years. Rothschild, it will be remembered, argued that part of publicly supported research should be regarded as applied research, which should by rights be paid for by the ultimate beneficiaries (called customers), whose proxies would be government departments. So, when the British government accepted the formula, nearly a half of the council's budget (which proportion has since shrunk), was transferred to departments such as agriculture (interested in environmental consequences of fertilizer usage), the environment (interested in the environment) and energy (interested in natural resources). With the passage of time, departmental interests have been attenuated, and their willingness to pay for research has correspondingly declined. So the research council, to keep its establishments occupied, has been forced into the market, selling itself as a research contractor.

Earlier this week (see p.307), the council was rightly boasting of its success in selling its technique of side-scanning sonar to the US Geological Survey, which has commissioned it to carry out a survey of the continental shelf off the United States. Now the technique has been licensed to a British company which will, no doubt, be able to establish a profitable business elsewhere overseas, from which the council will also (rightly) profit. But there are other fields in which the council's success as a contractor for research has not been as welcome. Thus the British Geological Survey, originally established so as to provide the United Kingdom with a knowledge of the rocks and resources on which it rests, has been forced by penury to set up as a contractor for a wide variety of geological survey work, much of it well within the field of competence of private geological survey companies. This is one of the minor bones of contention that will no doubt be dealt with by the committee of inquiry now under way.

The perplexing question is how it can be right, even admirable, that the council should sell its sonar technology commercially while being criticized for competing with private organizations in geological survey work. The superficial answer is that there is a vast difference between a technique (such as side-scan sonar) where there are no immediate competitors and one (such as geological survey) where there are all too many. The more durable answer is that the role of publicly supported research enterprises working in the field of applications should be to stimulate companies working in the private sector, never to compete with them. It is probably a fault of the British economic system that there was no small company eager to build a future around the side-scanning sonar that is now a feather in the council's cap, in which case the council should have been worrying to stimulate a company of that kind. What is needed for the future is a mechanism for telling when public research must stop acting as an entrepreneur, becoming a midwife for others. □

US-Soviet fusion

US still vague about Geneva agreement

Washington

FUSION energy researchers in the United States were optimistic last week that the accord reached in Geneva between President Ronald Reagan and Soviet leader Mikhail Gorbachev on magnetic fusion would lead to increased contacts with their Soviet counterparts. Details of what exactly has been agreed were sparse last week, but the two leaders advocated "the widest possible international cooperation" on development of magnetic fusion power. There are still formidable obstacles, however, in the way of building a joint fusion research reactor.

Fusion research does not rank high

Honour for honoured

THE Technical University in Munich (TUM) is trying to woo back Klaus von Klitzing, winner of this year's Nobel Prize for Physics (see *Nature* 24 October, p.667) by offering him the directorship of a new institute in semiconductor physics. Setting-up costs for the institute are estimated at more than DM20 million, of which it is hoped industry will provide one-third, the other two-thirds coming from the Bavarian state government. Von Klitzing is said to have indicated interest, but is undecided about accepting.

From 1980 to 1984, von Klitzing was an associate professor at TUM but in a reorganization of the physics faculty he was not promoted to a full professorship, so he accepted a directorship at the Max Planck Institute of solid-state physics in Stuttgart. At the new institute, he would be a full professor and will have the opportunity to teach, which he is said to want.

The institute will be set up to provide the most advanced research facilities. It will be divided into three sections, each headed by a director — von Klitzing's colleague Frederik Koch, who proposed the original idea for the institute, has been invited to lead one of those sections. The plan also includes six scientists and nine technicians as well as administrative and secretarial staff. All of these are new positions and have to be included in TUM's next budget. Land is already available but finance for a new building and equipment will be discussed early in December when the state government meets with various industrial concerns.

The institute will be named after the Berlin physicist Walter Schottky. TUM intends to do all it can to lure von Klitzing back, not just because of his recent honour, but because it considers semiconductor physics an important field. Jen Altman

among the issues needing discussion between the superpowers, which perhaps explains the vagueness of the public statements, although further details may yet emerge. It will be for the Department of Energy to draw up detailed proposals for an agenda on collaboration, which could be discussed when Reagan and Gorbachev meet next year in the United States.

There are several reasons why magnetic fusion is a good candidate for international cooperation. Most of the literature is unclassified and the next generation of research machines (which will seek to attain plasma ignition, the point at which fusion becomes self-sustaining) will be enormously expensive.

The US magnetic fusion research budget, though faring well by comparison with other energy research projects, has declined substantially in recent years, from \$464 million in 1984 to \$429 million in 1985, with the budget for fiscal year 1986 down to \$382 million. The programme's goals have correspondingly been pushed into the future. Dr Harold Furth, head of the Princeton Tokamak Fusion Test Reactor, says that because of budget constraints, plans to introduce tritium (the fusion fuel) into the Princeton reactor have been put back until at least the end of 1988. No decisions have been made on a new research machine for the United States in 10 years. Cooperation with the Soviets would be one way to make a limited budget go further.

Soviet magnetic fusion research is comparable with that in the United States. Collaboration takes place at present under an intergovernmental bilateral agreement first negotiated in 1973 and extended in 1983. The number and the standing of scientists in reciprocal exchanges are, however, widely believed to have declined in recent years (partly because of protests over Soviet human rights abuses and its invasion of Afghanistan). There were six scientific teams exchanged last year. Dr Frank Press, president of the National Academy of Sciences (NAS) (whose personal efforts to further individual US-Soviet exchanges have been criticized by anti-Soviet hardliners in the Pentagon) said the Reagan-Gorbachev agreement will affect exchanges "productively".

In the short term, there are likely to be many benefits from increased cooperation on basic plasma physics research and on design and engineering of fusion equipment and diagnostics. But if increasing the frequency of scientific visits is a feasible goal, there remain serious difficulties for cooperation on a fusion reactor. Dr John

Richardson of NAS says that a role can be seen for two machines, one to demonstrate plasma ignition and a second to examine engineering concepts for a future commercial reactor. And there are several ancillary projects that might be tackled as collaborative ventures, such as compact toruses, magnetic mirror fusion and hybrid reactors whose neutron flux would be used to manufacture fuel for conventional fission reactors.

But Richardson can see no "natural division of labour" for a truly international four-way agreement to include Europe, the United States, the Soviet Union and Japan; so far, it has not even been possible to negotiate such a deal with Europe.

Tim Beardsley

Geneva summit

Soviet optimism on fusion plan

THE Soviet response to the prospect that the Geneva summit could lead to increased scientific cooperation has been slower than that in the United States, but is no less enthusiastic. Mr Mikhail Gorbachev himself has been reluctant to "deal with the nuances" of possible cooperation projects, as he phrased it at Geneva last week, preferring to stress the funds that could be released to fight world hunger if the arms race were halted. Indeed, when he did commit himself on a specific project — fusion research — what he had in mind was not bilateral but multilateral cooperation. "It was decided", he said, "jointly to approach a number of other states about cooperation in the field of thermonuclear research. This is a very interesting idea which could guarantee for mankind an inexhaustible source of energy."

The view of the Soviet scientific community was reflected last week in Moscow by Dr Petr Timofeev, deputy director of the Institute of Geology of the Academy of Sciences, who said that the institute had been involved in a number of cooperation projects with the United States on the geology of the oceans which had, regrettably, been curtailed in recent years, but would now, he hoped, be renewed. Other potential fields of cooperation in which Soviet scientists are interested include space research, the "conquest of human disease", the environment (a delegation from the US Environmental Protection Agency visited the Soviet Union just before the Geneva summit) and, of course, controlled thermonuclear fusion.

If this cooperation project does materialize, it could prove a particular blessing to Academician Evgenii Velikhov, head of the Soviet nuclear fusion programme. Velikhov is a great advocate of international cooperation on fusion. It was he who put the proposal for the INTOR international tokamak project to the International Atomic Agency.

Vera Rich

US non-proliferation policy

Pact with China almost ratified

Washington

THE US Senate voted last week to approve President Reagan's controversial nuclear cooperation agreement with China, adding only some less-than-onerous certification requirements the President must meet to ensure that the agreement does not contribute to the spread of nuclear weapons. The Senate's approval is expected to be echoed shortly by the House of Representatives.

Opponents of the agreement have denounced it as a step backwards for the cause of nuclear non-proliferation: intelligence reports have been cited to support the claim that Chinese nuclear engineers have helped Pakistan to achieve a suspected nuclear weapons capability, and there have been reports of nuclear dealings with Argentina, South Africa and Iran. The agreement as signed by the President includes no formal non-proliferation safeguards, and critics say that this will encourage other countries to refuse to submit to non-proliferation safeguards.

The administration's answer is that China need not submit to safeguards because it is already a nuclear weapons state. The administration says that China has provided verbal assurances of its commitment to non-proliferation, but these have not been sufficient to quell anxieties in Congress. As recently as 1978, a Chinese leader publicly stated that all nations had the right to "nuclear strength".

More recently, China's position has changed: it has joined the International Atomic Energy Agency (IAEA) and in September announced for the first time that it would voluntarily open some of its civil nuclear facilities to IAEA inspectors. It will also apply IAEA non-proliferation provisions to its own exports.

Nevertheless, both the Office of Technology Assessment and the Nuclear Regulatory Commission have raised doubts about the agreement since it was introduced to Congress in July. Does it, for example, provide sufficient guarantees in the event of a serious deterioration of relations between the two countries? Although it specifies that prior mutual agreement would be needed before any US-derived nuclear fuel could be reprocessed or further enriched, many question how effective this would be if China wanted to process for weapons use stocks of nuclear fuel already on hand. And the agreement includes no clear US veto rights over exports of weapons-grade plutonium made from US fuel.

The sudden climb-down last week by opponents of the agreement seems to represent a simple recognition of political realities: to demand a substantially changed agreement that would require new negotiations with China would have needed an unlikely two-thirds majority in

Congress. Furthermore, any action would have had to be taken before 11 December, when the agreement is due to come into effect.

The modest requirements attached to Congress's approval are that the President must certify that nuclear technology and materials supplied to China will be used solely for their intended peaceful purpose, and that China will provide unspecified

"additional information" on its non-proliferation policy. In addition, the President must certify that US domestic law will be observed, and that requests for reprocessing approval can be granted or denied individually. The administration has cooperated with legislators on the wording of the certification requirements and is content with them; the way appears now to be open for US nuclear construction companies to compete with their European counterparts for contracts in the Chinese nuclear power programme.

Tim Beardsley

Television technology

Picture compression in sight

Princeton, New Jersey

SQUEEZING more television channels into a given bandwidth, every communication company's objective, is also high on the list of RCA's objectives. The company's research laboratories here are designing a novel electronic test unit that will double the number of television channels that can be carried by a satellite transponder.

The computer-controlled unit will show how well imperfect television signals, with some picture frames entirely missing, can be regenerated at the receiving end. To begin with, the tests will be conducted omitting every second frame of a complete television transmission. They will then be extended to see whether the system will work when more than half the signal is not transmitted.

The technique, called Motion Adaptive Interpolation, relies on a computer algorithm to reconstruct the missing frames. A less refined version of the system has been operating since 1983 on the telecommunications satellite, Satcom V, built by RCA to carry television signals to Alaska. Signals at the receiving end are regenerated from signals from which half the frames are missing, but the quality is poor. RCA considers that substantial improvements would be needed if the system were to be used for television traffic within the mainland United States.

RCA now operates five telecommunications satellites, and plans to launch two more by the end of the year. Roughly half the traffic consists of television transmissions between the major television networks and their affiliated stations and between programme suppliers and cable networks.

Predictably, processing television signals from which every other frame is missing imparts a jerky motion to moving objects. The machine on which RCA is working would store successive frames in such a transmitted signal and then, by interpolation between the positions of moving objects, reconstruct the missing intermediate frame.

If the development proves successful, RCA plan to use the system on its video-conferencing links and would also expect

suitable computing machinery to be installed at the head-ends of cable television networks, at the points where signals are received from linking satellites for onward transmission through the network.

Another spur to these developments is the general concern for the design of television receivers for the 1990s, on which several manufacturers are working. One likely development is that of digital transmission of the information required for each picture element (pixel), which among other advantages, will allow colour and luminance information to be transmitted separately, allowing greater control of picture quality.

Part of the development now under way is psychologically based; RCA wants to know how the human eye perceives motion in a sequence of two-dimensional images. The research group has provisionally worked out a scheme whereby it is not necessary to compare entire television frames to detect motion in one relative to the other. Instead, a sequence of progressively more rudimentary frames is constructed by omitting alternate rows and columns of pixels from a frame; the hope is that it will be possible to identify significant motion in the most rudimentary of these digital pictures, thus reducing the amount of data to be handled by the computers. It may then be feasible to incorporate enough processing capacity into individual television sets.

The same principle of data compression is being used in the development of a "smart" camera which may be used as a means of detecting only significant movement within its field of view.

Used as an automatic surveillance system, the camera is controlled by a modest microprocessor whose limited capacity is nevertheless able to detect movement in the most rudimentary of the sequence of collapsed frames and then to arrange to inspect a more informative frame in the hierarchy on the succeeding cycle of operation. RCA hopes that the US National Aeronautics and Space Administration will use the system as a motion detector in the gravity-free environment of the space cabin.

Bill Johnstone

Palaeoanthropology

All human life is there

EVEN the most hard-bitten hominid-fossil watchers were impressed by the specimens unveiled last week at the Commonwealth Institute in London. Centrepiece of the exhibition "The Human Story" is a sequence of candidates as human forefathers ranging from *Aegyptopithecus* and *Ramapithecus* through the australopithecines to *Homo* in his/her various forms.

An australopithecine, of the same type as Lucy, the skeleton found in Ethiopia by US anthropologist Don Johanson.

The skulls are boldly displayed so that the visitor can touch them, with mirrors beneath allowing examination of the teeth in a way that would make a dentist feel at home. Pride of place among the fossil exhibits goes to the 1.6 million-year-old *Homo erectus* skeleton WT15000, discovered last year by Kamoya Kimeu near Lake Turkana in Kenya and described in *Nature* in August (316, 788-792; 1985). Kimeu was on hand at the opening of the exhibition to explain that the skeleton on display is a replica — very convincing right down to the Kenya Museum accession numbers in black ink — and that the original is locked away in the Kenya National Museum, safe from the hazards of air travel and public exposure. Back in the museum too are more teeth, eventually destined to rejoin the rest of WT15000.

Another famous hominid fossil, "Lucy", is present in skeletal form and also as one of the life-size figures, reconstructed on the basis of the latest anatomical and cultural data. Lucy, or at least, a

female *Australopithecus afarensis* from around 3.2 million years ago, is to be seen reaching up, hypothetically and bipedally, to gather fruit from a bush. It was a hard life for *A. afarensis*, it has been deduced from their fruit-eating ways and tendency to die off at an average age of 22, hence the wasted appearance of the reconstructed figure.

By the time the human line gets to 100,000 years ago, the reconstructed figure looks far meatier in the form of Neanderthal man. Not the clumsy colossus that has stubbornly survived in popular fiction for many years, but a character looking not unlike a modern-day middle-weight boxer, though one who has had a long career of mismatches.

The first question asked by many visitors to the exhibition seems to be "But

when did they become us?", and the exhibits and catalogue give a good guide to the various possible answers. But the question more likely to be in the visitor's mind at the end of the exhibition is "Has it finished?". After the impressive series of fossils and figures, and stone tools you can play with, comes a dash through recorded history and a bank of flickering television screens, with all four UK channels in quadruplicate or more, apparently representing the present. And then some conspicuously blank walls — the future is unknown, you see . . .

The exhibition owes much to sponsorship by IBM and in February it will take to the road, with stays in Amsterdam, Stockholm, Bremen, Paris and thence to Africa for display in Ghana, Nigeria, Senegal and Kenya.

Charles Wenz

"The Human Story" is at the Commonwealth Institute until 23 February 1985. Details from Commonwealth Institute, Kensington High Street, London W8 6NQ, UK

French education

Stoking the university fires

JEAN-PIERRE Chevènement, French minister of education, plans to double the number of potential university entrants in France by the year 2000.

This could make France an extraordinary place in which to be educated in the 21st century, for already there are a million students in French universities, compared with, for example, only 175,000 university students in Britain. In Britain, fewer than 5 per cent of the population are considered likely to benefit from university education; but in France, by the end of the century, 55 per cent of 17-year-olds could have the coveted "baccalaureat" or "bac" that would give them the right to enter university.

Whether they will enter university, however, is another question. Chevènement's plans include extending the bac — or bacs, as there are half-a-dozen different specializations — into more career-oriented and technical directions. Politically, he wishes to extend the opportunity of gaining the cachet of a "bac" to the largest possible number of children (at present only a third attempt it, a fraction he would like to increase to four-fifths by the year 2000); educationally, he wants to see a work-force better oriented to the demands of 21st century technology. Thus by 2000, the plan is that many who succeed at the bac will not be going to university, although they will have the right, but straight into work, in a new, high-technology France.

Hence if enough work exists in 2000 (at present many unemployed French school-leavers spend a year coasting in university), the universities need not be much larger by that date. But Chevènement plans to increase the number of qualified school leavers to cope with the changing teaching

load, and a figure of 4,000 new teachers a year has been mooted. Some 400 new schools are also to be built.

Further, Chevènement is to loosen the stranglehold of mathematics on French education, much to the disgust of the mathematicians who consider that mathematical ability is essentially a test of intelligence. Thus the volume of mathematics teaching even in the coveted bac-C (mathematics and physics) is to decrease, and in other bacs it will become less abstract and oriented more to the needs of the central disciplines. (For example, in the "management" bac, bac-B1, mathematics will emphasize statistics and economic calculations.)

Among French scientists, reaction is mixed to the proposal to "dilute" mathematics. Biologists favour the move, claiming that many potential biologists are swamped in school by the mathematical demands of the science bacs; but physicists and mathematicians fear a fall in student quality. Chevènement, for his part, has no desire for the number of potential French Fields Medallists to fall.

Chevènement's planned school reforms cannot take effect before autumn 1986, however, by which time a right-wing government will probably be in power. Nevertheless, the minister's plans may not be forgotten. Many of his educational reforms, including bringing back the Marseillaise and improving discipline in primary schools, have gone down better on the right than the left. And Chevènement, once the darling of the left, has made no secret of the fact that he would accept an offer to continue his work, even under a right-wing prime minister. An imaginative conservative government might just agree.

Robert Walgate

US defence research

Will Congress cut SDI?

Washington

AN apparently unending series of exposures of fraud and waste in the Department of Defense (DoD)'s procurement division, coupled with anxiety over the federal budget deficit, is prompting Congress to take a tough line with defence spending this year. One of the casualties is likely to be the Strategic Defense Initiative (SDI), President Reagan's programme of research into anti-ballistic missile defences. Non-SDI research, however, is blooming.

The President's request of \$3,700 million for SDI in fiscal year 1986 (which began on 1 October) has been rudely refused by the House of Representatives, which has offered a mere \$2,500 million. The Senate has not finally made up its mind, but the figure of \$2,960 million has been urged by a committee. (The figure in 1985 was \$1,400 million.) Despite the apparently large increase from 1985, the SDI organization is far from happy, and has made plain to Congress that support at the level that now seems likely will lead to delays of a year or more to key demonstrations.

But if strategic defence research is now in question, other basic research supported by DoD is likely to increase substantially in 1986. This budget item request (known as line 6.1 to insiders) was \$971 million, which is likely to be met or even exceeded. Last year the figure was \$860 million. Historically, roughly half of the 6.1 budget, and some of the more applied 6.2 research, has been spent in universities. The increase for basic research continues a trend established more than ten years ago. This year, however, the Department of Defense has a new pot of money for university research that it is asking to have filled, the University Research Initiative (URI). Responding to widespread concern about the state of science education and research at US universities, the department went to Congress to ask for \$25 million for URI in 1986; the programme would support fellowships and the like at DoD laboratories as well as university research in risky but potentially profitable areas such as materials and structures, fluid mechanics, biotechnology, communications and optical networks. Congress was so impressed with the proposal that a Senate committee voted a total of \$100 million for URI (and DoD has quickly decided that it will, after all, be able to use the lot). This is on top of a \$30 million per year university instrumentation programme and \$500 million of direct research support last year. Even Colonel Donald Carter, acting head of DoD's research and advanced technology division, one of whose jobs is to drum up support for DoD university research on Capitol Hill, admits that

"we're doing quite well this year". But the House of Representatives has so far agreed only to the original request for \$25 million; a compromise will be worked out with the Senate next month.

Universities, despite their perpetually uneasy relationship with DoD because of friction over the issue of research secrecy, are not unnaturally delighted that DoD is "taking the university research infrastructure seriously", according to Robert Rozenzweig, president of the Association of American Universities. But the high-principled association still objects to the addition of inoffensive sounding amendments to other legislation, including DoD appropriations, that seek to provide funds for specific research projects or facilities at particular institutions, usually within the constituencies of the sponsors of the legislation.

Pork-barrel legislation has a distinguished history in the United States. Some 34 projects were supported in this way between 1983 and 1985, according to data

compiled by the association. But Rozenzweig and Robert Clodius, president of the National Association of State Universities and Land-grant Colleges, say that if allowed to proceed unchecked, direct funding of research facilities which circumvents peer-review procedures will "undermine the very system that has made our research enterprise the envy of all other nations". The presidents are lobbying congressional committees to eliminate all pork-barrel amendments.

Among the beneficiaries of current proposed pork-barrel amendments (in a number of different bills) are: Syracuse University (\$12 million); Oklahoma State University (\$1 million); Rochester Institute of Technology (\$11.1 million); Northeastern University (\$13 million); University of Nevada (\$3.5 million); University of South Carolina (\$4 million); East Michigan University (\$2 million); University of Missouri (\$450,000); New York University (\$2.6 million); Tufts University (\$1 million); and Pennsylvania State University, the University of Minnesota and Massachusetts Institute of Technology (each to receive one-third of \$1.7 million).

Japanese audiotechnology

Renoir returns from the dead

Tokyo

IF you want to hear about the Impressionist school of painting, who could be better to listen to than Pierre Auguste Renoir who, along with Monet, was its most famous exponent? The only problem is, of course, that Renoir died in 1919. But thanks to a little modern computer technology this proves to be a trifling objection — at least in Japan.

To help advertise a major exhibition of the Impressionists being held in Tokyo until the middle of December, callers can hear about the philosophy of Impressionism from Renoir himself by dialling Tokyo 320-3000. The voice is the product of the Japan Acoustics Research Laboratory and its construction relies both on the ability to analyse and manipulate sound patterns with the aid of computers and the ability to predict fundamental voice characteristics through knowledge of an individual's anatomy.

According to the institute's director, Dr Masumi Suzuki, many of the major characteristics of a voice are governed by the structure and shape of the oral and nasal cavities and the resonances they produce in air set vibrating by the vocal cords. Of course, regional accents and the like are not shaped only by such parameters, but the characteristics that enable one to recognize a voice independently of its accent are. The structure and shape of the oral and nasal passages can themselves be measured relatively easily from an X-ray. Where such data are not available, they can be predicted with less accuracy from de-

tailed measurements of the face and neck.

Once the details of the vocal tract are available, simulation proceeds through use of a computer model. A human voice is input (reading French in Renoir's case) and analysed spectrographically. A computer model of the effect of the different resonances produced in different regions of an individual's vocal tract is then used progressively to modify spectral components of the input voice. The result, in Renoir's case, is a new voice that still, according to native French speakers, is perfectly accented French but has (lacking evidence to the contrary) acquired the characteristics of Renoir's voice.

But the "science" of voice analysis does not stop there. If a voice can be predicted from a face, why not a face from a voice? Some researchers have had a try with one of Japan's most wanted criminals, the self-styled "man with 21 faces" who extorts money from confectionery manufacturers by placing poison in bars of their chocolate on sale in supermarkets. All that is known about him is the sound of his voice on tapes and recorded calls. Despite the production of a portrait based on his voice, however, his arrest has moved no closer.

Patriotic Americans are not forgotten either in famous historical figures whose voices have been brought back from the dead. One can hear Abraham Lincoln proclaiming "Fourscore and seven years ago our fathers brought forth on this continent a new nation . . .", in tones to which his high and slightly bent nose apparently contributed a great deal. **Alun Anderson**

UK computing

Prospects good and bad

By the United Kingdom's own rather sad standards, computing research in universities is doing relatively well. Sir Keith Joseph, Secretary of State for Education and Science, this month gave the Computer Board for Universities and Research Councils an extra £1 million for 1986–87, to be followed by £2 million for each of the next two years, to enhance Janet, the wide area network that will connect computers in all universities, research council sites and polytechnics. Although the demand by researchers for computing facilities far exceeds resources, the Computer Board continues to make a relatively successful case to the government for increased support, most recently in its three-yearly report (see below).

In the private sector, computer companies themselves are finding life difficult, but the manufacturing industries are greatly increasing their use of computers. A survey of more than 2,000 engineering companies, sponsored by the Department of Trade and Industry and published this week*, shows that nearly 60 per cent of

UK board reports

THE report of the UK Computer Board for Universities and Research Councils, published this month (Cmd 9671, HMSO, £3.30), covers the period April 1983 to March 1985. During this time, the board was mainly concerned with supporting local computing facilities for research and teaching in universities, supporting national facilities and promoting the efficient sharing of resources. The most important developments were the extension of supercomputing facilities in the two national centres and the development of Janet, the wide area network connecting all research establishments. The board has also taken a lead in developing standards and encouraging the use of computers for teaching in universities. Reappraisal of some of its methods has been caused by its observations of developments in the United States and Japan.

During the next few years, the board will re-examine its relationship with the University Grants Committee (UGC) and will assess its priorities for what it sees as the two ends of a spectrum — supercomputers for the specialized research user and workstations for the undergraduate user.

A joint working party with UGC and the Advisory Board for the Research Councils has set up two subgroups; one, chaired by Professor A. MacFarlane (Cambridge) will examine the scientific need for advanced computing facilities and the other, chaired by Professor E. Spratt (Kent) will examine technical options for meeting that need, particularly in collaboration with industry.

Maxine Clarke

UK engineering plants are using or are about to use computers. In 1986, the industry plans to spend £250 million on software and £600 million on hardware, mainly on minicomputers and mainframe computers rather than micros. John Butcher, Under Secretary of State for Industry, says that the United Kingdom may be leading Europe in the uptake of computers for engineering purposes, "although European data are hard to come by".

The most widely used applications of computers in industry are in manufacturing management and mechanical design, although computer-aided design and draughting are the fastest-growing applications. The top-selling microcomputers are IBM personal computers, XTs and ATs; Apricot is a poor second with only half as many installations as IBM.

IBM is the largest manufacturer of computers in the United Kingdom, and, according to a forecast published last week*, although the company's activities contribute to import savings, UK computer companies are growing too slowly. "The prospects for ICL [Britain's nationalized computing company] are less clear now that the government has largely abandoned its 'buy British' policy and the outlook for small computer companies is extremely volatile", according to Cambridge Econometrics' model. The deficit on the balance of payments for office machinery and electronic data-processing equipment rose from £200 million to £1,100 million between 1980 and 1983 (current prices).

Cambridge Econometrics expects industry's investment in computing equipment and export demand to increase by 4 per cent per year for the next 10 years; by the end of the century, the demand for office machines and data-processing equipment will still be the highest for all manufacturing industry in Britain. But British companies are unlikely to be taking advantage of these opportunities.

The study suggests that new domestic and foreign entries to UK production during the next few years may improve the viability of the industry, but it says that "we do not see enough evidence at the moment to build such hopes into our central forecast". Large companies at present involved in other areas of electronics, particularly military applications, could enter the civilian computer market, or more foreign companies could locate European production centres in Britain. But these remain hopes rather than predictions.

*Third Annual Engineering Computers' Survey in Engineering Computers, November 1985; Prospects for Computers and Office Machinery in the UK to the year 2000 Cambridge Econometrics forecast 85/2. Price £500.00 from PO Box 45, 21 St Andrews St, Cambridge CB1 2EX, UK.

UK space centre

Space programme coordinated

BRITAIN last week re-entered the international space arena with the announcement of its National Space Centre (NSC), to be based in London. The first director general of the centre is Roy Gibson, who was also the first director of the European Space Agency (ESA), for a three-year period. NSC's initial budget is £100 million a year, or about one-fifth of the French government's space budget.

The purpose of the centre, a concept that the Minister for Industry Geoffrey Pattie has taken the lead in promoting, is to coordinate Britain's fragmented space programme, which at present includes projects sponsored by the Department of Trade and Industry (DTI), Ministry of Defence (MoD), Science and Engineering Research Council (SERC) and Natural Environment Research Council (NERC). But "no change in policy" has occurred with respect to ESA; NSC is intended to make Britain's contribution "more efficient".

The first task for NSC is to develop a long-term strategy for Britain's space effort by coordination of industrial, defence and scientific users of space, who will be able to influence the policy of the centre by "financial and in-kind contributions". NSC's first projects will be based at the Royal Aircraft Establishment, Farnborough (where DTI and MoD already have programmes) and at SERC's Rutherford Appleton Laboratory, the present focus of the academic space programme in Britain.

Professor Bill Mitchell, chairman of SERC, welcomed the formation of NSC last week on behalf of SERC and NERC. The main interests of the research councils are astronomy from outside the atmosphere and remote sensing. SERC, NERC and DTI already collaborate on the latter.

The centre will not be involved in the US Strategic Defensive Initiative "at this stage" — the largest proposals with which it is at present concerned are whether, as a member of ESA, to take part in the US space station planned for the 1990s and whether to support the development of the novel reusable launch vehicle *Hotol* in collaboration with the private sector.

Britain pulled out of Europa, its collaborative space venture with France and Germany, 25 years ago. Since the failure of that project, France has taken the lead in the development of Ariane, now a commercial competitor of the US space shuttle. Although Britain's effort has a long way to go before catching up with other countries with space programmes — not only France and the United States, but also Japan, West Germany, Italy and India — the creation of NSC is a step in the right direction.

Maxine Clarke

AIDS in Japan

No screening of blood donors

Tokyo

OVER the centuries, Japan has fought off foreign invaders with a fervour second to none, but in the face of an invasion of AIDS (acquired immune deficiency syndrome), Japan has been slow to protect the purity of the national blood. The AIDS virus has already made significant inroads into the blood of certain sectors of the Japanese population. Yet there are still no plans to introduce routine screening of blood donors as in the United States and Britain.

The number of confirmed cases of AIDS in Japan has risen to eleven since March, when the first two cases were reported among haemophiliacs (*Nature* 315, 8; 1985). Six of the eleven were or are homosexuals and five haemophiliacs. Two of the homosexuals and four of the haemophiliacs had died by late October according to the Health and Welfare Ministry.

Many more Japanese are known to have been exposed to the virus. In September, a team at Jutendo University headed by Takao Matsumoto found that the blood of 5 out of 103 homosexuals contained antibodies to the AIDS virus, HTLV-III (human T-cell lymphotropic virus), while in October the Health and Welfare Ministry revealed that, of 395 haemophiliacs surveyed across the nation between September 1984 and this summer, 120 or 31 per cent have been exposed to AIDS, probably through treatment with blood plasma products from the United States. With about 5,000 haemophiliacs and 300,000 homosexuals in Japan, estimates of those already exposed to AIDS runs into tens of thousands.

In response, the Health and Welfare Ministry has announced plans to double the amount of blood taken from individual donors to reduce dependence on imported blood plasma (*Nature* 317, 101; 1985), but earlier this month, in reply to an inquiry by a communist member of the House of Representatives, the ministry said there is at present no need for mandatory AIDS screening of blood donors. Instead, "voluntary" testing will be covered by the health insurance system for "high-risk" groups such as homosexuals and drug addicts. But in Japan, where pressure to conform is severe, a rush of volunteers can hardly be expected.

Blood donors in Japan are routinely tested for hepatitis virus and venereal disease, which may have induced homosexuals to give blood in order to get free VD checks. A month after the release of the findings by the team at Jutendo University, the Health and Welfare Ministry directed the Red Cross Society to stop accepting blood from homosexuals.

Amid calls for mandatory AIDS tests for blood donors come appeals for the

introduction of screening for another less notorious but equally insidious virus, HTLV-I, which causes ATL (adult T-cell leukaemia). Yorio Hinuma of Kyoto University's Institute for Virus Research estimates that a million Japanese are now carriers of ATL virus. Although the normal infection route is from husband to wife and from mother to child, Hinuma suspects that each year as many as 40,000 Japanese may be "artificially" infected with ATL virus by blood transfusion. Only one in a thousand carriers usually develops the disease but for those who do, ATL is almost invariably fatal, with 50 per cent succumbing within six months and the rest within two years. Professor Hinuma stresses, however, that there is very little relation between the ATL virus HTLV-I and the AIDS virus HTLV-III, and he considered the HTLV-I, II, III terminology proposed by Dr R.C. Gallo, chief of the tumour cell laboratory of the US National Cancer Institute, to be inappropriate.

As in the case of AIDS, the Health and Welfare Ministry has turned down requests for mandatory screening of blood donors. In both cases, the cost of screening the 8 million people who donate blood in Japan each year appears to be the major deterrent.

David Swinbanks

More AIDS money

Washington

ALARM over the spread of acquired immune deficiency syndrome (AIDS) was evident in an agreement of funding for the US Public Health Service reached last week in Congress. The report established a special fund of \$70 million for combating the disease to be allocated by the director of the National Institutes of Health (NIH); this is in addition to the \$120 million the administration had requested for AIDS research at NIH. The total sum appropriated under the agreement would be \$5,501 million, an increase of 7 per cent over last year's figure, with 6,100 new and competing extramural research grants — substantially more than the 5,000 the administration wanted. The total support for AIDS research throughout the Public Health Service is expected to be more than \$300 million.

The agreement, which has not yet been formally accepted by either arm of Congress, notes that there is an urgent need for more basic research on AIDS and directs NIH to spend "a substantial portion" of the extra \$70 million on basic research. The director of NIH is urged to convene a special working group of both intramural and extramural researchers to decide priorities for such research, which would also report to Congress.

Tim Beardsley

Soviet spaceflight

Medical hazards to cosmonauts

THE illness of Vladimir Vasyutin, which led to the premature return to Earth of the latest long-stay crew of Salyut-7, has been provisionally diagnosed as "an inflammatory disease that did not respond to the drugs available on board". Although Vasyutin was unable to act as commander during the landing, he was well enough to give a brief television interview after touchdown. The doctor who gave him a preliminary check-up said that his condition was "satisfactory", but that he would nevertheless need hospital treatment.

Valerii Kybasov, himself a cosmonaut, told a TASS correspondent that it was decided to bring Vasyutin back to Earth simply because "in our country, man comes first". There have been some hints in the Soviet media, however, of fears that the malady might have spread to his fellow crew members, Viktor Savinykh and Alexandr Volkov. An unnamed official, interviewed at the landing site by Moscow radio, spoke with some concern of an ordinary cold having developed "into some new forms", requiring "urgent intervention from Earth. Both Savinykh and Volkov proved to be in good health, however.

This is the first major medical incident in almost 25 years of Soviet manned spaceflight, although there have been cases of toothache and colic which responded to the on-board medicine chest. Even if Vasyutin's indisposition proves relatively minor, his hospitalization could have important repercussions for the Soviet space programme. The lobby within the Soviet space programme pressing for a flight to Mars claims that the long-term Salyut missions have already established the human organism's adaptation to prolonged weightlessness without permanent after-effect. Vasyutin's illness will provide the "conservatives" who oppose the lobby with a powerful example of their main counter-argument, that space medicine has not yet reached the stage where cosmonauts can be allowed to venture out of reach of a base hospital.

Vera Rich

● Two Syrian trainee cosmonauts have arrived in the Soviet Union to prepare for a future joint mission. This news has caused some speculation among Baikonur-watchers, since even a few months ago, Soviet space officials were emphatic that no further "international" flights were being planned. Even more curiously, the news was announced in *Krasnaya Zvezda*, the Red Army daily. It has been suggested, therefore, that the invitation to Syria to participate in such a flight may be a sop, not unrelated to the tentative political rapprochement of the Soviet Union towards Israel. □

British environment research

From penury to mere poverty?

THE Natural Environment Research Council (NERC), the most friendless of Britain's four science research councils, is hoping that the tide of misfortune is beginning to turn. Mr Hugh Fish, the council's chairman, said earlier this week that he hopes, in the next two weeks, to have assembled the funds (\$2.5 million a year) that will enable Britain to join the new international Ocean Drilling Program being organized by the US National Science Foundation (NSF). The council has also won a modest success in the commercial exploitation of the sea-bed profiling system called GLORIA and hopes that a modest share of the extra £14 million made available for the research councils two weeks ago will allow it to increase its support for university research.

British membership of the Ocean Drilling Program (ODP) has been a thorny issue for most of this year. The hope, now, is that the necessary sum will be raised by means of contributions from industry (mainly the oil companies), government departments and from NERC's own budget. According to Mr Fish, a British delegation has been invited to the next meeting of ODP, in Hawaii in the second week of January, as observers, but he hopes they will be able to attend as paid-up members.

NERC's success with GLORIA (which stands for Geological Long Range Inclined Asdic) rides on a contract with the US Geological Survey last year for the survey of the bottom topography of part of the US economic offshore zone. Now, according to NERC, the contract has been extended to include virtually all of the offshore United States under a six-year contract that will cover, among other things, the development of improved equipment at the Institute of Oceanographic Sciences. At the same time, NERC has arranged to "capitalize on the opportunities presented by this unique British research module" by means of a contract with Marconi Underwater Systems, which have the right to build versions of the asdic system and to provide an underwater survey system overseas. The company apparently expects there to be some £5 million worth of business each year, and is committed to share some of the benefits with NERC.

A statement put out on Monday with the council's annual report for 1984-85 says that the decline of the value of research commissioned by government departments from council institutes, the chief cause of NERC's money problems in recent years, has now been reversed; last year, income of this kind amounted to £24.9 million, compared with £23.7 million in the previous year. Mr Fish said that he hoped the figure will increase as further opportunities for commercialization arise.

But NERC's hopes of winning public support for the costs of restructuring, the research council euphemism for persuading people to retire early, were disappointed; it asked for £2 million, but received only £1.25 million.

Mr Fish and his senior colleagues on Monday repeatedly emphasized how important it is that NERC's research should be commercialized. By means of a sales office in Brussels and an agent in Washington, the council hopes to win extra business from overseas companies and governments, "which is not to suggest that British government departments will not always be important customers". But there are obvious benefits in diversity. "We've had our fingers burned", said one official.

Meanwhile, NERC plans to introduce a more formal system for the assessment of its own activities by the three criteria of timeliness; potential economic and social benefit to the United Kingdom; and the enhancement of Britain's reputation overseas. There is to be a process by means of which the outcome of research decisions will be judged retrospectively by these criteria, with the objectives both of evaluating decisions made and of refining the criteria.

For the immediate future, NERC hopes to increase its support for university research, by about £5 million a year on its present spending, estimated at close on £17 million, counting the cost of research vessels maintained by NERC. Mr Fish says that university research is especially desirable because of its flexibility; people will do "basic research on a short-term basis".

Dr John Bowman, secretary of the council, also said on Monday that there was a case for increasing NERC's interests in atmospheric chemistry, partly so as to make good the loss of support for acid precipitation research some years ago but also for more general reasons. The council also plans "a more sophisticated approach to forestry" and says it has already written to the new director of the National Space Centre (see p.305) to declare its interest in remote sensing of various kinds.

On the research council's future organization, Mr Fish said that a new version of its corporate plan was about to be shown to members of staff for their comments, and would be finally discussed by the council in January. On this occasion, he said, the plan would be more concerned with science than with organization, which would nevertheless not be substantially changed from that in the document published earlier this year.

The council is pushing ahead with the appointment of three scientific directors to oversee the different parts of the council's programme; one is in post and two are

about to be appointed. But it may be decided that these persons should be sited in laboratories and not in the council's headquarters. The future of the British Geological Survey, the largest of the council's dependants, would be decided only after the committee on the subject under Sir Clifford Butler had reported, although Mr Fish gave it as his opinion that the survey needs more money to support its "core" programme.

Last year, the council's total income was £93.4 million, of which £65.3 million was contributed by the general science budget, which supports all the research councils. Although contract research is seen as a growing component of the budget, Mr Fish says that NERC has now learned a lesson from the painful withdrawal of government contracts in recent years, and intends not to employ full-time members of its staff on short-term contract work. □

French experiment on coma patient

FRENCH doctors experimented on a patient who had been in a coma for three years, it was reported in France last week amid a storm of protest. The patient, a young man who was claimed to be "brain dead", has since died, but not, it is claimed, as a result of the experiment, which involved a high-speed blood transfusion into a pelvic bone.

The doctors are reported to have undertaken and announced the experiment to provoke debate on the ethics of such operations, and this objective they have certainly achieved. Thus Louis René, president of the ethical commission of the French medical association, has said he was "profoundly shocked" to hear of the experiment. "Since 1947 at Nuremberg — a symbolic date and place — doctors have affirmed that experiments can only take place with the agreement of the subject", René wrote to the newspaper *Le Monde*. In the case of a patient in coma, this agreement is patently impossible and so experiments on comatose patients should be forbidden, he wrote. Such experiments "treated the patient as an object and denied him all human character", exemplifying "condemnable medical imperialism".

Following this line, Edmund Hervé, minister of health, has demanded an inquiry and cited article 18 of the French medical code which forbids a doctor to subject a patient to unjustifiable risk.

Le Monde, however, quotes a somewhat different view from M. Guy Tiercelin, president of a national anaesthetics commission. "I am not necessarily opposed to an experiment if there is proof of brain death", said Tiercelin. "One could test certain techniques of reanimation, but one must be very vigilant, for we should never perform experiments on patients who may recover".

Robert Walgate

Japanese psychiatry

SIR—The article by Alun Anderson entitled "Abuse for visiting scientists" (*Nature* 315, 361: 1985) contains some noteworthy misunderstandings, and as one of the parties concerned we would like to clarify matters.

Protest action taken against the seventh congress of the Japanese Society on Biological Psychiatry at Gifu was not directed at the visiting scientists from the United Kingdom and the United States. The protest was made in order to obtain open public discussion on the ethics of an experiment on a human fetus carried out by Professor Masayuki Namba of Gifu University and his followers. Professor Namba, the president of the congress, was responsible for the human experiment in his capacity as director of the Department of Neurology and Psychiatry in Gifu University. But he chose to avoid discussion and to cancel the congress.

The Japanese Society on Biological Psychiatry is managed under a highly closed, almost secret system. For example, a non-member who wished to join only for the days of the congress at Gifu had to obtain a written recommendation from one of the board of directors, even though the names of directors and the address of the office are not usually announced. The society has no ethical code governing experiments involving human subjects. We have examined the summaries of papers that were to be delivered at the Gifu congress and past congresses and find evidence of many unethical experiments. So we would like to give a warning about the true nature of the society. The issue of the human experiment at Gifu is now under investigation by an *ad hoc* committee of the Japanese Society of Psychiatry and Neurology but we understand that the doctors involved in the experiment are unwilling to cooperate.

We, the Psychiatrists' Union of Tokyo University, aim to reform the present state of psychiatry in Japan and to that end will take action against unethical psychiatric conduct. A liaison group, including some of our members, has been pressing for open discussion about the Gifu experiment. This group is not, as Anderson wrote, the "antipsychiatrists within Tokyo University". Nor did this group intend to visit the smaller meeting at Nagoya. It is also not correct to describe us as "antipsychiatrists" as there are differences between our views and those of the antipsychiatrists found in the United Kingdom and Europe in the 1960s and 1970s.

Anderson states that there is no evidence of unethical conduct by the outpatients ward doctors of the University of Tokyo hospital. Why is he so dogmatic? Anderson has mentioned the horrific incidents that occurred at Utsunomiya hospital. But the outpatient doctors have long been closely connected with the Utsu-

nomiya hospital as has been widely reported in the Japanese press.

For example, the director of the Utsunomiya hospital set up an outpatient clinic near Tokyo University hospital and the outpatient doctors made use of this clinic for practice and research. Some patients were sent from this clinic to the Utsunomiya hospital. It is a fact that many of the outpatient doctors visited the Utsunomiya hospital to work or for research and contributed to the hospital's development. Many further connections exist.

The miserable state of Japan's mental hospitals as mentioned in Anderson's article is a social problem for the nation. It stems partly from the relationship between university mental hospitals as suppliers of new doctors and other mental hospitals. Many university hospitals treat the mentally ill as research objects and think little of their rights. This trend is closely related to the abuses seen at Utsunomiya where patients were forced to remain in hospital for long periods and were dominated by violent methods.

Furthermore, the government supports this situation through the Japanese Mental Health Act because few legal rights are given to patients, especially those admitted to mental hospitals. Visits from Disabled Peoples International, the International Commission of Jurists, and the International Commission of Health Professionals are necessary and important. These visits are expected to have a favourable influence upon mental health policy in Japan. We regret to say, however, that a large number of Japanese psychiatrists take attitudes similar to the outpatient doctors of Tokyo University. Reform is still far off. To be reconciled with the outpatient doctors is not easy for us at the present.

Slighted Dallas

SIR—In his appreciation of the 1985 Nobel Prize award in Physiology or Medicine to Michael S. Brown and Joseph L. Goldstein (*Nature* 17 October, p.569), Peter Newmark has indulged either in the subtlest of *Nature's* ironies or an insult that cannot have been intended by so sympathetic a commentator. Newmark points out that "So far all attempts to lure both of them from their opulent Dallas surroundings to more distinguished institutions have failed". As a longtime admirer not only of our new laureates but of the remarkable medical school in which they work, permit me to suggest that it might be hard, indeed, to identify "more distinguished institutions". Considering the high level of innovative science that is con-

ducted at the University of Texas Health Services Centre in Dallas, I look forward to Newmark's revised estimate of Dallas as more of her sons share the dais with the King of Sweden.

Irrigated tomatoes

SIR—I would advise Michael Andrews (*Nature* 17 October, p.570) not to drink water containing 3,800 micrograms of selenium per litre. As Paracelsus said, "the dose alone determines the poison", and a woman who took about 27,300 micrograms of selenium daily for 2 months had toxic symptoms¹. No increase in symptom and disease reporting was found in a population drinking water containing 494 $\mu\text{g l}^{-1}$ of selenium². Andrews does not report the selenium content of the tomatoes he filmed in July, which he wanted to eat. If they were irrigated with water from the California Aqueduct, the water was reported³ in the same month to contain 0 to 2 $\mu\text{g l}^{-1}$. Information on selenium content of common foods is supplied by Underwood⁴.

Evolving journal

SIR—Your review of *Molecular Biology and Evolution* (*Nature* 26 September, p.296) contains two errors. In one, your reviewer asserts that *Molecular Biology and Evolution* "has not expanded since its first issues". The five issues of 1984, the special inaugural issue of December 1983 not being included, totalled 366 pages or 73 pages per issue. The six issues of 1985 totalled 560 pages or 92 pages per issue. That is a 25 per cent increase. That, together with the fact that, in its first year, *Molecular Biology and Evolution* circulation surpassed that of the excellent 14-year-old *Journal of Molecular Evolution*, suggests, contrary to your reviewer's report, that *Molecular Biology and Evolution* has already established itself alongside its worthy competitor.

Bergmeyer **Methods of Enzymatic Analysis**

The Nutcracker in Enzymatic Analysis...

...is an indispensable aid for
biochemists, chemists, food scientists,
nutritionists, and others working with enzymes.

Or, as George M. Whitesides, Harvard University, has put it: "For the past twenty years the first step in any enzymatic analysis has been to consult Bergmeyer. The next years will be no different: the updated and enlarged third edition of Hans Ulrich Bergmeyer's 'Methods of Enzymatic Analysis' ...promises to play the same role as previous editions..."

Rapid developments in molecular biology and immunology have necessitated the rearrangement and expansion of the third edition of Bergmeyer's "Methods of Enzymatic Analysis". Originally conceived as a 10-volume work, it now comprises 12 volumes:

Vol. I: Fundamentals (1983)
Vol. II: Samples, Reagents, Assessment
of Results (1984)
Vol. III: Enzymes 1 (1984)
Vol. IV: Enzymes 2 (1984)
Vol. V: Enzymes 3 (1984)
Vol. VI: Metabolites 1 (1984)

Vol. VII: Metabolites 2 (1985)
Vol. VIII: Metabolites 3 (1985)
Vol. IX: Proteins and Peptides (1985)
Vol. X: Antigens and Antibodies 1 (1986)
Vol. XI: Antigens and Antibodies 2 (1986)
Vol. XII: Drugs, Pesticides (1987)

Testing for cystic fibrosis

It has at last been made on the development of a prenatal test for cystic fibrosis. At first, it will only be useful in some families.

A BATCH of papers published in this issue of *Nature*, together with a paper in the current issue of *Science*, signal the beginning of the end of the hunt for the cystic fibrosis gene, defects of which are responsible for the disease. Although the gene remains to be identified, at least it is now certain that it resides in the middle of the long arm of chromosome 7, within a region that comprises no more than about 1 million base pairs. And the new data offer immediate prospects for the prenatal testing for cystic fibrosis.

Approximately one in twenty Caucasians carry a defective cystic fibrosis gene, and about one child in 2,000 inherits such a gene from both parents and consequently dies of the disease, usually by the age of 30. Despite the frequency of the disease, nothing has been learnt of the gene (or genes) in which the defects arise and no gene product has been convincingly demonstrated. It has not therefore been possible as yet to devise a prenatal screening test for cystic fibrosis relying on the detection of the defective gene or its product. An alternative approach, laid out in detail by Botstein *et al.* (*Am. J. hum. Genet.* **32**, 314; 1980), is to look for and find a restriction-fragment length polymorphism (RFLP) close enough to the cystic fibrosis gene to act as a linkage marker.

An RFLP is no more than a variation in DNA sequence that generates or abolishes a recognition site for a restriction enzyme. Because these enzymes cut through double-stranded DNA, the positions of their recognition sites on a stretch of DNA determine the sizes of the "restriction fragments" of DNA they generate. The chromosomes of any homologous pair are bound to differ by many RFLPs, which can therefore, in principle, be used to tell which of the pair of chromosomes carries, for example, a defective cystic fibrosis gene. If the RFLP is located closely enough on the chromosome to the cystic fibrosis gene not to become separated from it by the normal process of genetic recombination, it will also serve as a linkage marker for the defective gene. Because the RFLP is only a linkage marker, rather than a direct assay of the defective gene, it cannot be used for population screening but only predictively, in family studies.

It has been calculated that if RFLPs are more or less evenly distributed along and among the chromosomes and are

"informative", no more than 150 would be sufficient to provide one closely linked with any gene. So far, however, although several hundred useful RFLPs have been found and many have been localized, they are not evenly distributed and most are informative for only a minority of families. In searching for a linkage gene that could be on any chromosome, it therefore makes sense to begin with the chromosomes that are most saturated with RFLPs and conventional markers (such as different forms of serum enzymes). In this way, by the middle of 1985, several research groups had excluded about 40 per cent of the human genome as the site of the cystic fibrosis gene.

The first sign of success came at the Eighth International Gene Mapping Workshop in Helsinki in August where Hans Eiberg, of the University Institute of Medical Genetics in Copenhagen, reported a tentative link between cystic fibrosis and a form of the serum enzyme paraoxonase (an aryl esterase). Eiberg calculated that the paraoxonase gene and the cystic fibrosis gene lie within ten million base pairs of each other. However, this linkage — now published by Eiberg and others in *Clinical Genetics* **28**, 265; 1985 — was less useful than it might have been because paraoxonase is poorly characterized and the chromosomal localization of its gene is unknown. Rather than dampening the enthusiasm of those who had failed to find an RFLP linkage, Eiberg's result revived their flagging energy.

Among those searching for an RFLP were Lap-Chee Tsui and colleagues at the Hospital for Sick Children in Toronto. In July of this year they came to an agreement to test some of the 200 or so useful RFLPs generated by Collaborative Research Inc. Much to their joy, and purely by chance, a cystic fibrosis-linked RFLP turned up among the first half a dozen RFLPs that Tsui tested. The result was reported at the American Society of Human Genetics meeting in October, and has just been published in *Science* (**230**, 1054; 1985).

What was not reported at the meeting was the chromosomal localization of the RFLP, information that would immediately have enabled others to concentrate exclusively on any RFLPs that they knew to be associated with the chromosome in question. Members of both the Toronto and Collaborative

Research teams say that they had only preliminary evidence at the time and were not prepared to risk presenting a faulty localization in public. Nevertheless, a rumour emerged that their RFLP was on chromosome 7, as they confirm on page 380, although other rumours pointed towards different chromosomes.

Spurred on by the rumours, two other research groups have now found RFLPs that are linked to cystic fibrosis and report them on pages 322 and 384. One of the groups is centred on Bob Williamson's laboratory at St Mary's Hospital Medical School in London. Its RFLP probe is an "anonymous" DNA probe on the long arm of chromosome 7. Williamson's group also reports linkage between the cystic fibrosis gene and two other chromosome 7 genes — that for the T-cell receptor beta chain (p.384) and a collagen gene (*Lancet* 29 November p.1241). The linkage reported by the other group, centred on Ray White's laboratory at the Howard Hughes Medical Institute in Salt Lake City, is to an RFLP that is in the locus of the *met* gene, which is a human oncogene on the long arm of chromosome 7 (see p.285). The overlap between the various probes locates the cystic fibrosis gene in the middle of the long arm of chromosome 7.

Both Williamson's and White's RFLPs are much more tightly linked with the cystic fibrosis gene than is Tsui's. His RFLP is probably no closer than 15 million base pairs (0.5 per cent of the human genome) to the gene. Williamson's and White's are each within about a million base pairs of it, conceivably very much closer. The greater the distance between the RFLP and the gene, the greater the chance that they will be separated by recombination during meiosis, confounding attempts to use the RFLP as a prenatal diagnostic marker of the defective gene. In these terms, Tsui's RFLP is not diagnostically useful, whereas the other two are. What is likely to emerge, when the dust settles, is a set of markers which will make the reliable prenatal diagnosis of cystic fibrosis a reality assuming that all cases are due to a mutation of the same gene.

Both to develop a screening test that avoids the need of family studies and to discover the fundamental basis of cystic fibrosis, vigorous attempts will now be made to identify the gene itself and to find out what it produces. **Peter Newmark**

Evolutionary theory

Hamilton's rule OK

From Alan Grafen

THE darwinian principal of natural selection was extended by Hamilton in 1964 to the evolution of social behaviour¹. This extension is central to much of today's evolutionary biology, but it is something of a sport among mathematical biologists to cast doubt on its validity. Now David Queller, writing on page 366 of this issue², presents a simple and powerful derivation of Hamilton's result that should go some way towards convincing the sceptics.

Hamilton's extension to darwinism is enchantingly simple and has come to be known as 'Hamilton's rule'. In an uncomplicated world, the morphology and behaviour of an individual would affect the number of offspring it had in its lifetime but not the number of offspring other individuals had. Given that individuals do interact, though, the question is how will selection cause animals to value each other's reproduction? Will they place no value on it — that is, will selection favour forms according only to their own number of offspring? Or will they place equal value on their own reproduction and that of others — that is, will selection favour those forms that produce more offspring in total for the species? Hamilton's answer was intermediate between these two ex-

trems. He showed mathematically that natural selection would act so that one individual would value the reproduction of another according to how closely the two individuals were related. Identical twins would value each other's offspring equally with their own; brothers and sisters would value each other's offspring half as much as offspring of their own; and so on. The evolution of a social trait then depends on an 'inclusive fitness' calculation, in which all the effects of the trait on reproduction are added together, weighted by the appropriate relatednesses. Relatedness matters because relatives share more genes than non-relatives, and natural selection is a matter of the nonrandom survival and proliferation of some genes at the expense of others.

Hamilton's rule is simple, but is it true? There is a whole literature (reviewed in more detail elsewhere³) that tries to answer this question. Queller's contribution is to provide a very simple and direct proof of Hamilton's rule, as an antidote to what I feel is the biologically unsympathetic and over-mathematical treatment that is usually applied. The positive feature of Queller's approach is that it sacrifices an element of mathematical rigour for the

sake of deriving a much more general result, and deriving it with clarity and simplicity.

Complete recursion, or dynamic sufficiency, is the element of rigour sacrificed by Queller's approach. In a simple model (one locus, two alleles) in a diploid species, we can say that a rigorous model uses the frequencies of all three genotypes in one generation to predict all three genotype frequencies in the next. Complete recursion is the use of those genotype frequencies for predicting the genotype frequencies in the following generation, and so on. Queller's method has an incomplete recursion, because it uses all three genotype frequencies in one generation to predict the frequencies of the two genes in the next. Without making some assumption

(usually that the Hardy-Weinberg equilibrium holds), genotype frequencies cannot be calculated from gene frequencies, and so it is impossible to apply Queller's equations repeatedly to predict gene frequencies in succeeding generations.

That is the cost of Queller's simplification. Whether it is serious depends on one's point of view. One view is that incomplete recursions are unsafe, because to predict gene frequencies into the future they must make some false assumption (such as Hardy-Weinberg), and since the consequences of the assumption may not be innocuous, the only way to provide a secure argument is not to make the assumption in the first place. But not all conclusions that we draw from evolutionary models depend on predicting gene frequencies in the future. Queller's model predicts whether a character increases or decreases from one generation to the next, and shows that it depends on a form of Hamilton's rule. He makes no claim about dynamic sufficiency (although he does unguardedly claim his model is "exact", a term usually reserved for completely recursive models), nor is any needed for his conclusion to be both interesting and important.

The advantages gained by forgoing complete recursion are great. Since Queller's model does not specify what causes the genetic similarity between donor and recipient, his result holds whether the cause is a recent common ancestry, heterogeneity of the population, or the tendency of individuals to interact preferentially with like genotypes for other reasons. His interactants need not comprise mutually exclusive and exhaustive groups. Completely recursive models are hard work: they assume (contingently, not necessarily) mutually exclusive and exhaustive groups, and they must specify exactly how genetic similarity is caused. For example, a model in which each group comprises half siblings would be quite different from one in which each group was formed by picking individuals at random from two sets of full siblings. Queller's approach shows that the relatedness is one quarter in each case, and so the two are immediately seen to be essentially similar. Completely recursive models would be very different and — though for no very clear reason — would eventually give the same answers as each other (and as Queller's model) in the matters important for the evolution of a character. The models would differ in details of interest to the population geneticist: for instance, they would have different kinds of polymorphic equilibria when the two alleles were so similar in effect as to be empirically indistinguishable.

While, in my view, Queller's trade-off leaves him as a champion of Hamilton's rule in one battle, he has been too ready to concede defeat on its behalf in another. Hamilton's rule was first derived for additive social interactions, in which the

Long-running experiments (I)

Only six drops have fallen, the latest in April 1979, since this experiment was set up in 1930. Its aim is to demonstrate and measure the fluidity and very high viscosity of pitch. The experiment, which continues in the Department of Physics at the University of Queensland, Australia, is one of three long-standing experiments considered in detail in the *European Journal of Physics* 5, 193–200 (1984), along with a request for accounts of further examples.

effects of others on one individual's number of offspring simply added up. What if interactions combine synergistically, as Queller calls it? The problem here is one of measurement. The third, synergistic, term in Queller's form can be made to disappear by agreeing to define benefit and cost as the average effects on individual's fitnesses, rather than as arbitrary terms in a model of fitness¹.

So in Queller's simple model, Hamilton's rule, with costs and benefits correctly understood, is perfectly adequate for deciding the direction of change in gene frequency. In more complex models, in which individuals can pay costs and receive benefit many times in a lifetime, a real problem of non-additivity can arise. But one way round this is to make the plausible assumption that the gene effects in question are small: Fisher's microscope argument⁴ — that near to a good design only small changes are likely to be advantageous — suggests that, in the final stages of the perfection of a character, only genes of small effect matter.

Thus, for genes of small effect, additivity is restored and the correctness of Hamilton's rule is restored with it¹. (Population geneticists may be interested in genes of large effect, and it is perfectly reasonable to doubt if characters are anywhere near perfection, so not everyone will be happy with this assumption. Note that a gene can have a small effect through rarity of expression even if it has a large effect on the occasions it is expressed.)

The method used by Queller is Price's covariance selection mathematics, a powerful technique of general value¹ that was originated and expounded by Price in brief articles^{5,6}. For Queller, the value of

the technique was that it enabled him to change easily from counting genes in offspring according to the individual producing the offspring (the usual population genetics method of accounting by results), to counting according to the individual whose genotype caused the existence of the offspring (the inclusive fitness method of accounting by control).

In closing, I must mention a paper unjustly neglected by Queller, in which Price's method was first applied to inclusive fitness problems. This remains the most general and satisfying derivation and justification of inclusive fitness, at the same time as being remarkably simple. Queller cannot appeal to the obscurity of the journal in which the paper appeared, but he can plead for clemency on the grounds that its author himself later neglected the existence of his own strong and powerful result. Readers may have guessed that the author in question is W.D. Hamilton^{7,8}. His hitherto unsung primacy in providing a simple and rigorous justification for inclusive fitness, together with his well-recognized provision of the idea in the first place, inspire me to end close to where I began: Hamilton rules OK! □

Developmental biology

A reversible epithelium

from Jared M. Diamond

EPITHELIA are the sheets of cells that line body cavities such as the intestinal lumen. They are responsible for active transport of specific solutes, either from lumen to blood or vice versa depending on the particular solute and epithelium. In most cases the direction of transport is fixed, even though the rate of transport may be subject to physiological regulation. On page 368 of this issue G.J. Schwartz, J. Barasch and Q. Al-Awqati describe an unusual case of a reversible epithelium, which can transport the same solute in either direction in response to physiological need. The whole arrangement of pumps, exchangers and vesicles within the epithelial cell is reversible in detail. The tissue not only is a curious violation of the usual rules but also offers a promising system for learning how epithelia become programmed during development.

Schwartz *et al.* have studied the inter-

calated cells of the cortical collecting tubule (CCT) in the kidney. These regulate blood pH by either secreting H⁺ and absorbing HCO₃⁻, or secreting HCO₃⁻ and absorbing H⁺. The main physiological stimulus converting the tubule from net HCO₃⁻ secretion to net H⁺ secretion is the acid load. Schwartz *et al.* identify H⁺-secreting or HCO₃⁻-secreting cells by the endocytosis of fluorescent markers from the luminal or blood surface of the tubule, respectively. Since epithelial cells are commonly found to transport a given solute in a fixed direction, one might expect the CCT to contain two H⁺/HCO₃⁻-transporting cell types with opposite functions and the mitotic proliferation (or transport rate) of each cell type to respond to pH levels. Instead, mitotic figures are absent in intercalated cells of acid-loaded animals and the total number of cells remains virtually unchanged — 137 per mm

Depending on the respective locations of an ATPase and an exchanger, controlled by the acid load, the intercalated cell of the cortical collecting tubule either secretes H⁺ (left) or HCO₃⁻ (right).

of tubule after loading, compared with 129 per mm before loading. But the number of acid-secreting cells increases 10-fold, from 7 to 74, and the number of HCO₃⁻-secreting cells decreases correspondingly, from 122 to 63. This is evidence for a change in direction of transport in the same cell, rather than proliferation of a cell type with a certain direction of transport.

The change of direction is a result of the simple reversal of the arrangement of the transport mechanism, which consists of a proton-pump ATPase at one cell face and a Cl⁻/HCO₃⁻ exchanger at the opposite face (see figure). In H⁺-secreting cells the ATPase is at the luminal membrane and the exchanger at the blood-facing membrane; these locations are reversed in HCO₃⁻-secreting cells. The ATPase originates from intracellular vesicles which fuse with either the luminal or the blood-facing membrane, so that the ATPase is inserted into the appropriate membrane. Thus, one critical link in the control of transport direction by acid load is control of direction of vesicle movement.

These experiments open the way to exploring other steps in the chain of controls in the CCT. Insertion of the Cl⁻/HCO₃⁻ exchanger has not been studied and the detailed time course of acid control of ATPase insertion is not yet known. But this study also has broader significance for the developmental biology of epithelia in general. Biologists have long wondered how the genetic information in a radially symmetrical egg becomes translated into radially asymmetrical cells, tissues and animals. In epithelia, this question is posed in a particularly simple form, as functions are segregated between two cell faces. Membrane biologists have learned much about the details of the transport mechanism at each face but have so far paid little attention to developmental questions of how each mechanism gets inserted into the 'right' end of the cell. Having a cell in which the direction of insertion can be experimentally reversed may make it easier to answer questions such as these.

Jared M. Diamond is Professor of Physiology at the University of California Medical School, Los Angeles, California 90024, USA.

Particle physics

How to detect solar neutrinos

from W. Hampel

EXPERIMENTS designed to observe the neutrinos produced in the fusion reactions in the interior of the Sun provide the only way to test the theories of energy generation in stars. Another motivation for solar-neutrino experiments comes from particle physics: they may be the only possible way to obtain information on neutrino mixing (oscillations), a question of great importance in Grand Unified Theories. This is because neutrino mixing could be observable only in experiments with very large source-detector distances. Two recent papers^{1,2} put forward a new concept for a solar-neutrino detector and evaluate its ability to detect neutrino oscillations.

Neutrino mixing occurs if neutrinos are superpositions of two or more mass eigenstates with different rest masses. This leads to oscillations of the electron neutrinos, ν_e , produced in the Sun with neutrinos of other flavours (muon- or tau-neutrinos, ν_μ or ν_τ) on their way from the Sun to the detector. In fact, the discrepancy between the theory and observation for the only solar-neutrino experiment carried out so far, the Brookhaven Chlorine Experiment³, may be due to neutrino oscillations. Whether this is true or not will be decided by the outcome of the Gallium Experiment⁴, the only other solar-neutrino detector that has had its feasibility demonstrated in a pilot experiment.

Since both chlorine and gallium detectors employ the radiochemical technique that is based on inverse β decay, they are sensitive only to ν_e and measure the integrated (above their respective energy thresholds) energy spectrum of solar neutrinos. Therefore, they give only partial information on neutrino oscillations (through a depleted rate compared to that expected without oscillations)⁵. To learn more about neutrino oscillations, it will be necessary to use a detector able to give direct information on the energy spectrum of solar neutrinos. The detector proposed by Cabrera *et al.*¹ has this feature. It is based on the elastic scattering of neutrinos from electrons. Figure 1a presents the spectrum of the proton-proton (pp), ^7Be and ^8B solar-neutrino sources (the other solar-neutrino sources are less important and have been omitted from this figure) along with the recoil electron spectra expected for these sources from the $\nu_e + e^-$ reaction. Solar-neutrino detectors based on this reaction have been proposed before (for example, refs 6 and 7). In these proposals, the detection of the recoil electrons is through their Cerenkov radiation in water. This method, however, is restricted to high energy (≥ 5 MeV) recoil electrons and thus only allows observation

of the ^8B neutrino component (see Fig. 1).

The detection method suggested by Cabrera *et al.* is completely different. It is based on observing the temperature change of a macroscopic silicon mass (of the order of 1 kg), when a recoil electron is produced through a neutrino interaction and deposits its energy in the silicon block. For instance, a 100 keV recoil electron would raise the temperature of 1 kg Si from 1 mK to about 4 mK. This principle,

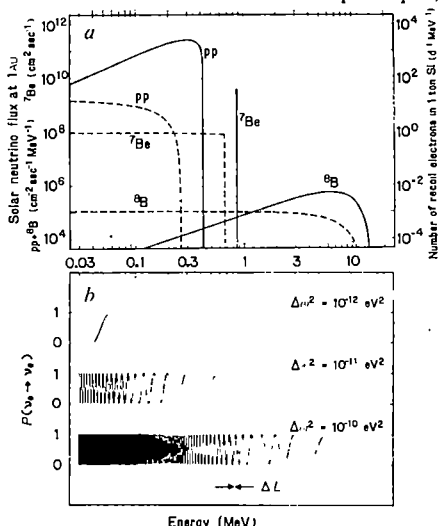

Fig. 1 a, Energy spectrum of the solar pp, ^7Be and ^8B neutrinos with the corresponding recoil electron spectra produced in the $\nu_e + e^-$ reaction. b, Probability $P(\nu_e \rightarrow \nu_e)$ of an electron neutrino ν_e emitted in the solar core reaching a terrestrial detector as ν_e . P as a function of neutrino energy is plotted for different Δm^2 .

the bolometric detection of solar neutrinos, was first investigated by Drukier and Stodolsky⁶ but their proposal was based on the coherent scattering of neutrinos from nuclei through the neutral current interaction and on a different technique (superconducting grain detector).

There are two major problems connected with bolometric detection of neutrinos. One is the problem of measuring small temperature changes in the mK region. The other is how to reduce the background to the very low level required for the detection of neutrinos. Concerning the temperature measurement, Cabrera *et al.* suggest, for instance, using superconducting thin film, such as tungsten deposited on the surface of the Si block. Determination of the resistance of this film would provide a measure of the temperature with a precision of about 10 keV in the energy range 10 keV–2 MeV.

Background is the more severe problem; the difficulties may be even larger with bolometric neutrino detection than with other types of detectors, since deposition of energy in the keV to MeV range is

not at all specific to neutrinos. All radiations, either from radioactive impurities in the Si itself or from outside sources (α -, β -, γ -radiation, neutrons, cosmic-ray particles), can dissipate energy in this interesting range and thus mimic a neutrino-scattering event.

As a first step, Cabrera *et al.* suggest constructing a prototype detector using a single Si block (~ 1 kg) and studying its properties with non-neutrino sources. Next, a larger detector (~ 100 kg) would be built for use in a reactor anti-neutrino experiment. Finally, a solar-neutrino experiment is planned with about 10 tons of Si ($\sim 10,000$ single cells).

Assuming such a detector could ever be built, what could be learnt from it about solar-neutrino oscillations? Restricting the discussion to the case where mixing of the ν_e occurs with only one neutrino of another flavour, the important quantity is the probability P that a ν_e emitted in the centre of the Sun is still (or again) a ν_e when it arrives at the detector:

$P(\nu_e \rightarrow \nu_e) = 1 - \sin^2 2\lambda \cdot \sin^2(\pi L \Delta m^2 / 2.48 E_\nu)$, where λ is a mixing angle ($0 < \lambda < \pi/4$), L is the distance between source and detector ($L = 1 \text{ AU} = 1.5 \times 10^{11} \text{ m}$), $\Delta m^2 = |m_1^2 - m_2^2|$ is the difference of the squared masses of the two involved neutrino mass eigenstates, in eV^2 , and E_ν is the neutrino energy in MeV. $P(\nu_e \rightarrow \nu_e)$ as a function of the neutrino energy is shown in Fig. 1b for maximal mixing ($\lambda = \pi/4$) and three different values of Δm^2 . Thus, the original solar-neutrino spectrum Φ (Fig. 1a) is modulated as a function of energy with P yielding ΦP as the ν_e spectrum incident at the detector site.

Neutrino oscillations affect the recoil electron spectrum produced by the $\nu + e$ reaction because the cross-section for ν_e is about six times larger than that for neutrinos of other flavours. This is because the neutral current (exchange of Z^0 bosons) contributes to the cross-sections for neutrinos of all flavours, whereas the charged current (exchange of W bosons) affects the $\nu_e + e^-$ reaction only. Thus, neutrino oscillations result in reaction rates that are depleted compared with the situation without oscillations. An advantage is that this comparison can be carried out separately for the different solar-neutrino sources (in contrast to the case for radiochemical detectors). This is especially useful for the pp neutrinos, since their reaction rate in the absence of neutrino mixing can be predicted rather reliably without use of detailed solar models. Measurement of the depletion in the pp reaction rate thus yields P averaged over the pp-neutrino spectrum.

The most important quantity to be determined is Δm^2 . As can be seen from Fig. 1, different values of Δm^2 affect the ν_e spectrum incident at the detector in different ways. For the continuum ν sources, this in turn has an impact on the shape of the resulting recoil electron spectra. Thus, careful examination of these spectra

should reveal Δm^2 and, combined with the information on P , the mixing angle λ .

Among other interesting effects discussed by Krauss and Wilczek² (such as the modification of vacuum oscillations by matter effects) there are two concerning the nearly monoenergetic ^7Be neutrinos. The first occurs because the distance L between the Sun and Earth varies by 3.4 per cent in the course of the year due to the eccentricity of the Earth's orbit. Trivially, this leads to a $1/L^2$ variation of the total solar-neutrino flux at the Earth. Because the equation for P depends on L , this variation also causes a periodic horizontal displacement of the P -curves in Fig. 1b, with an amplitude indicated in Fig. 1 by ΔL . Thus, the ^7Be recoil electron rate is expected to vary in time with a period and an amplitude depending on both Δm^2 and λ , an effect observable for $\Delta m^2 > 10^{-10} \text{ eV}^2$ and values of λ that are not too small.

The second effect is not related to neutrino oscillations. Since the electrons captured by ^7Be nuclei in the solar core have a Maxwellian velocity distribution depending on the local temperature T , the ν_e

emitted in this capture reaction have a spread in energy ($\sim 1 \text{ keV}$). Hence, the ^7Be recoil electron spectrum in Fig. 1 does not have a sharp cutoff at its endpoint energy. A measurement of the exact shape of this spectrum near the endpoint energy thus allows determination of T (requiring, of course, an energy resolution better than 10 keV).

Clearly, although the solar-neutrino detection suggested by Cabrera *et al.* and other detectors with similar capabilities in neutrino-energy spectroscopy are still far from being built, it would be well worthwhile investing in their development. \square

Vertebrate palaeontology

First marsupial fossil from Asia

from Michael J. Benton

MARSUPIALS, pouched mammals like kangaroos and opossums, are today restricted to Australia and the Americas (Fig. 1). How this split distribution came about has been much debated by biogeographers. A northern dispersal route was favoured at first, with the early marsupials travelling from the Americas across Asia to Australia, but no evidence of marsupials had been found at that time in Asia. The acceptance of continental drift led most people to prefer a southern dispersal route from South America to Australia via Antarctica (Fig. 2). Now that evidence of a fossil marsupial has

been reported from central asiatic USSR¹, the question is again open.

The specimen is a single tooth, identified as a first or second upper molar from the right side of the jaw. It is very small (1.7 mm long by 1.6 mm across) and its closest affinities seem to be with the opossums (family Didelphidae, subfamily Didelphinae). It is most like a tooth of the European fossil opossums *Amphiperatherium* and *Peratherium*, and the North American *Herpetotherium*. The new Russian find comes from the middle of the Aksyr Formation, which is lowermost Oligocene (almost 37 Myr ago), in

the Zaysan territory in eastern Kazakhstan, central Asia.

The fossil record of marsupials was fairly simple until a few years ago. The oldest forms came from the late Cretaceous (84–65 Myr) deposits in North America, in which fossils are quite common. Up to 30 species of early marsupials have been identified in Alberta, Montana and Wyoming; these are divided into three families, two of which died out with the dinosaurs at the end of the Cretaceous period and the Didelphidae (opossums), which has survived to the present day. A few late Cretaceous marsupials have also been reported from Peru and Bolivia in South America.

In the subsequent Tertiary period, the didelphid marsupials spread to Europe, where they survived until the Miocene (about 20 Myr). In North America, the didelphids also become extinct in the Miocene but then reinvaded from South America about three million years ago. During the Tertiary, many new groups of marsupials arose in South America, including equivalents of sabre-toothed cats and some dog-like forms, but only three families still survive.

There are now 13 families of marsupials in Australia. The fossil record is sparse, with only a few odd teeth and jaws known from the late Oligocene, but there are more abundant and diverse remains from the Miocene onwards.

Three years ago, a South American marsupial (a polydolopid) was found in the Eocene deposits (about 40 Myr) of Antarctica², a find that seemed to support the theory of a southern dispersal route, with an ice-free Antarctica as the bridge between the southern tip of South America and Australia. Then, two years ago, marsupial remains in Africa were reported by two independent teams^{3,4}—but these are probably the remains of animals that wandered into Africa from Europe and thus do not help to disentangle the palaeobiogeography of early marsupial dispersal.

Although the Asian tooth may seem to provide support for the northern dispersal theory, it is approximately equivalent in age to the oldest known Australian marsupials, and so occurs too late to fit with the theory. It is also a didelphid, a European–American form, with no particular Australian affinities. Most probably the didelphids were at one time distributed more widely than has been thought and then died out without leaving any descendants in Europe, Africa and Asia. \square

Metamorphic geology

Tectonics of metamorphism

from Michael Brown

LARGE tracts of the continents of the Earth are formed by rocks which have undergone regional metamorphism — that is, their mineral assemblages indicate that they have been subjected to elevated temperatures and pressures at some time in their past. Typically, these areas are located in orogenic belts or Precambrian shields, and show an intimate relationship between metamorphism and tectonic deformation. Generally accepted tectonic settings for regional metamorphism are continental margins associated with subduction, such as the west coast of South America; island arcs, such as those of South-east Asia; and zones of continental collision, such as the Alps and Himalayas. But the Hercynian metamorphism of the Pyrenees does not fit easily into this framework, as it must be explained by a tectonic setting involving neither subduction nor continental collision. On page 330 of this issue¹, S.M. Wickham and E.R. Oxburgh use data from the Pyrenees to formulate a model of continental rifting, with or without strike-slip movement, as the setting for regional high-temperature metamorphism.

Fig. 1 *a*, P - T paths followed by rocks buried initially at 70, 50, 40 and 30 km after overthrusting (after Fig. 6c of ref. 6). A-S, andalusite-sillimanite facies series; K-S, kyanite-sillimanite facies series; and, J-G, jadeite-glaucophane facies series. *b*, Uplift P - T path followed by rocks initially metamorphosed at 800°C and at 35 km depth undergoing approximately adiabatic decompression; rate of uplift 2 mm per year (after model B of Fig. 9 of ref. 15). A-S and K-S as in *a*.

Metamorphic terrains commonly develop as paired belts, in which one member is characterized by blueschists and eclogites, which indicate low temperature and high pressure conditions and which is interpreted as having been developed at a site of low heat flow, such as a subduction zone; the other member is characterized by high-temperature metamorphism and the development of migmatites and anatectic granites, and is interpreted as having been developed at a site of high heat flow, such as that beneath an associated volcanic arc. In detail, regional metamorphic terrains have been classified by their mineral assemblages into facies series types such as andalusite-sillimanite, kyanite-sillimanite and jadeite-glaucophane. It is implicit in this classification that an entire metamorphic terrain can be described by a single geothermal gradient and that higher-grade mineral assemblages develop from lower grade ones similar to those now found along the present erosion surface. This traditional view has been replaced by one in which individual rocks¹ and minerals² can be used to derive paths in pressure-temperature (P - T) space, which can be related to the tectonic setting^{3,6}. The loci of peak or slightly post-peak P - T conditions as preserved by the mineral assemblages — the metamorphic geotherm — results from the intersection of P - T paths for individual rocks with the erosion surface. It is this which is represented by the particular facies series.

Assuming that a uniformitarian approach to the problem is valid, we can try to unravel the tectonic history of metamorphic terrains by relating the characteristic features of young metamorphic belts to their tectonic settings. In essence, this means establishing the characteristic P - T paths of metamorphism in different plate-tectonic settings. For instance, the jadeite-glaucophane facies series can be generated by subduction. However, the Pyrenees comprise a series of structural and thermal domes with condensed metamorphic zonal sequences of the andalusite-sillimanite facies series, culminating in migmatites (rocks that have been partially melted) and abnormally high crustal temperatures and hence thermal gradients. It is this type of metamorphism that Whickham and Oxburgh explained.

Pioneering work on metamorphism associated with continental rifting and metamorphism due to magmatic accretion⁷ did not lead to a level of understanding of the thermal structure associated with such metamorphism comparable to our knowledge of overthrust terrains^{2,6}, although both are potentially important in

the island arc and active continental margin settings which so dominate lithospheric plate margin interactions. It is in this latter context that the work of Wickham and Oxburgh¹ is important.

Although it has been developed for a metamorphic terrain that cannot have formed at a subducting margin, the model has implications for high-temperature metamorphism in general, as extension and strike-slip movements are common in island arcs and active continental margins⁹. However, Precambrian meta-

Fig. 2 Typical texture produced by overstepping of reactions during approximately adiabatic decompression. In this case, garnet (black) plus quartz (medium grey in centre of view) reacts to orthopyroxene (granular mineral surrounding quartz crystal) plus cordierite (white to grey mineral in central part of view clearly replacing garnet); garnet-orthopyroxene-cordierite gneiss from the Sharyzhalgay Complex, USSR. Long dimension of photomicrograph is 5.5 mm, crossed polarized light.

morphic terrains such as the Napier Complex of Antarctica and the Arunta Complex of Australia, which have suffered extreme temperatures (900–950°C) and are characterized by approximately isobaric cooling to more moderate temperatures (600–650°C) during substantial periods of time, do not fit into a uniformitarian model of metamorphism based on plate tectonics theory. Moreover, the role of magma in regional metamorphism is poorly understood, although examples have been described from Greenland¹⁰ and Australia¹¹.

During continental collision, such as in the Alps, regional metamorphism may be related to crustal thickening, either by overthrusting or by uniform strain. The result is a characteristic anticlockwise loop in depth-temperature space (Fig. 1*a*), with one third or more of the P - T path being within 50°C of the maximum temperature achieved during burial and uplift⁶, and high-pressure metamorphism followed by increasing temperature and decreasing pressure.

More difficult to relate to tectonic setting with certainty are those terrains characterized by overstepping of reactions during decompression^{12–14} (Figure 2 illustrates an intermediate stage of a reaction). It is in the context of these metamorphic terrains characterized by approximately adiabatic decompression (Fig. 1*b*), that

the model for high-temperature metamorphism proposed by Wickham and Oxburgh¹ for the Pyrenees is important. Other essential features of the Pyrenean belt are the contemporaneity of sedimentation and metamorphism and the post-metamorphic development of granitoids in the lower crust. Such features are common in other high-temperature metamorphic belts such as British Columbia¹² and southern Brittany¹³, as well as in those found in Japan. The suggestion of Wickham and Oxburgh that the high-temperature member of paired metamorphic belts might develop by rifting and extension in island arcs is plausible and attractive. It is also timely, coming before a Royal Society meeting (January 1986) on Tectonic Settings of Regional Metamorphism. □

Human genetics

Measuring mutation in man

from Mary F. Lyon

GENETIC disease is an important cause of ill health and of physical and mental handicap, particularly in childhood, and results in a significant number of premature deaths. Major advances in preventing the birth of genetically affected children are being made, through genetic counselling, prenatal diagnosis and the use of recombinant DNA methods. But mutation remains a problem, resulting in the levels of many genetic diseases being maintained despite adverse selection, and it is becoming increasingly important to assess the possible increase in mutation rates caused by chemical or physical agents in the environment. At two recent meetings* plans were put forward for an international collaboration to measure the mutation rates in man by studying the offspring of cancer patients who have survived to reproduce after radiotherapy and chemotherapy. This should, for the first time, provide information on the effect of increased mutation rates on the incidence of hereditary diseases in man.

Genetic diseases may cause death before reproductive age, like Duchenne's muscular dystrophy, or result in failure to reproduce through, for example, severe mental defect due to fragile-X syndrome. Such diseases are maintained at their present frequency by a balance between fresh mutation and adverse selection. New mutations mean that affected individuals occur without any previous history of the disease in a family, making prenatal diagnosis of limited usefulness. Intensive efforts to clone the gene for Duchenne's muscular dystrophy were discussed recently in *Nature*^{1,2} and, when successful, will make it possible to prevent the birth of

affected sons to known carrier mothers. But one third of all cases are due to new mutation and the means of preventing these is unclear³, as it would be impractical to screen the whole population.

If the mutation rate rises, the incidence of such mutationally maintained diseases will rise, so efforts are being directed towards the detection of mutagens in the environment and their control or elimination. The International Commission for Protection against Environmental Mutagens and Carcinogens (ICPEMC) aims to evaluate scientific data relating to environmental mutagens and carcinogens and to provide information for estab-

lishing guidelines for regulatory or legislative action.

The question of detection and protection against germ-cell mutagens in man is highly complex. So far, successful methods of detecting changes in mutation rate directly in human populations have not been found⁴. Extrapolation from experiments is thus necessary, but this is only possible with data obtained in mammalian germ cells, because there are wide variations in the sensitivity of different cell types, which are not understood. Germ-cell data are laborious and costly to obtain and so are not available for many agents.

Relatively extensive information for several cytotoxic drugs that are used in cancer chemotherapy or as immunosuppressants does, however, indicate that some of these agents, for example cyclophosphamide⁵, are strongly mutagenic for certain germ-cell stages. With the recent improvements in the treatment of cancer occurring in children and young adults, many survivors of cancer treatment are living to reproduce. For the sake of the patients and their children there is a clinical need to know the long-term prospects, not only about the likelihood of second cancers in the patients but also about their fertility and the normality of their children.

Investigations into the reproductive histories of surviving cancer patients have already begun and preliminary results were presented at the first meeting. Examples include surveys of childhood cancer in Italy (G. Pastore, Turin), the United Kingdom (G. Draper, Oxford) and the United States (J. Mulvihill, Bethesda); of testicular cancer in Norway (S. Fossa, Oslo) and the United Kingdom, and of Hodgkin's disease in the United States (S. Donaldson, Stanford). In the

course of the meeting, it became clear that it would be very difficult for surveys in a single country to recruit sufficient patients and offspring to obtain meaningful results. Extrapolations from animal data suggest that many thousand offspring of patients treated with cytotoxic drugs will have to be studied to detect an increase in genetic disease resulting from such treatment⁶. Examination of survivors from atomic bomb explosions have also shown that large numbers are needed to detect the effects of radiation⁴.

At the first meeting, therefore, an international collaborative study was suggested, using a standardized protocol so that results could be pooled. A smaller group, including representatives of the Union Internationale contre Cancer, later met to formulate practical arrangements for initiating the study. The types of cancers to be studied would include childhood cancers, testicular tumours, and Hodgkin's and other lymphomas. Transplant patients and others treated with immunosuppressive drugs known to be mutagenic, such as cyclophosphamide^{7,8}, might also be included. Records would be kept of fertility, outcome of pregnancy including spontaneous abortions, birth weight, malformations and cancer in the offspring. Samples of blood would also be obtained from the patient, the other parent and the offspring, and stored in the hope that studies of chromosomes, protein (K. Berg, Oslo) or DNA variants would prove possi-

ble — potentially these could yield much more detailed information than records of clinical abnormalities⁹. At present, however, such studies are much more laborious and expensive; the DNA studies, though potentially the most informative, are also the most expensive (P. Pearson, Leiden).

Such a programme would benefit the patients and their offspring by providing information on the levels of genetic risk incurred from ever more aggressive cancer treatments. It is possible that the relative mutagenicity of different treatments could be assessed, so that the genetic risk could be reduced. Scientifically, the results could be compared with the extrapolations already made from animal work⁶ to assess the validity of such extrapolation. Most important, data would become available on the effects that known doses of strong mutagens have on germ-cell mutation in man. This will be a major step in tackling the problem of mutation as a cause of human genetic disease. □

Geophysics

International Geomagnetic Reference Field revision

from David R. Barraclough

THE International Geomagnetic Reference Field (IGRF) is a series of mathematical models of the main geomagnetic field and its secular variation. The models consist of sets of spherical harmonic (or Gauss) coefficients. IGRF has become widely used for deriving values of geomagnetic components used in, for example, studies of magnetic anomalies and investigations of charged particle motions in the ionosphere and magnetosphere.

Since it was first adopted by the International Association of Geomagnetism and Aeronomy (IAGA) in 1968 (IGRF 1965, ref. 1), IGRF has been revised three times: IGRF 1975 (ref. 2); IGRF 1980 (ref. 3); and now IGRF 1985. Details of the derivation of the original IGRF and of its development up to 1981 have been given by Zmuda⁴ and Peddie⁵.

The latest revision of IGRF was considered by Working Group 1* (analysis

of the main field and secular variations) of IAGA Division 1 during the Fifth General Assembly of IAGA held in Prague in August 1985. The following additions and modifications to IGRF 1980 were recommended.

- The extension of the definitive international geomagnetic reference field (DGRF) to 1980.0 by the adoption of a new model (DGRF 1980) to replace IGRF 1980.
- The addition of an international geomagnetic reference field for the interval 1985.0 to 1990.0 (IGRF 1985) consisting of a model of the main field at 1985.0 and a predictive model of the secular variation for use in adjusting the main-field model to dates between 1985.0 and 1990.0.
- The adoption of a provisional international geomagnetic reference field for the interval 1980.0 to 1985.0 (PGRF 1980), defined by linear interpolation between the coefficients of DGRF 1980 and IGRF 1985 (main field).
- The addition of a series of main-field

models for the epochs 1945.0, 1950.0, 1955.0 and 1960.0 (IGRF 1945, IGRF 1950, IGRF 1955 and IGRF 1960).

DGRF now spans the interval 1965.0 to 1980.0 with four main-field models for 1965.0, 1970.0, 1975.0 and 1980.0 (DGRF 1965, etc.). For dates between the epochs of the models, linear interpolation between the coefficients of the two models on either side of the date is to be used. A similar procedure is to be used for dates in the interval 1945.0 to 1965.0, using the IGRF 1945, IGRF 1950, IGRF 1955, IGRF 1960 and DGRF 1965 models, as appropriate. Extrapolation back to 1940.0 will probably be reasonably accurate, though this was not formally recommended by the working group.

Further revision of DGRF is not anticipated. The pre-1965 models (IGRF 1945 to IGRF 1960) will probably be replaced by definitive models in 1987. The newly adopted DGRF 1980 model replaces the former PGRF 1975 and IGRF 1980. The present PGRF 1980 will be superseded when a definitive model of the main-field at 1985.0, different from IGRF 1985, is adopted.

The main-field models for 1960 to 1985 have 120 coefficients each and extend to degree and order 10. The main-field models for 1945 to 1955 and the predictive secular-variation model have 80 coefficients and extend to degree and order 8. The coefficients are given in the Schmidt quasi-normalized form⁶ and refer to a sphere of radius 6,371.2 km. When converting between geodetic and geocentric coordinates the use of the international atomic unit (IAU) ellipsoid⁷ is recommended; this ellipsoid has an equatorial radius of 6,378.16 km and a flattening of 1/298.25.

The coefficients of the IGRF models and computer programs for synthesizing field values are available from:

oncor[®] Human *myc* Antibody

Oncor announces the successful development of affinity purified anti-human *myc*. This polyclonal sheep antibody has been qualified for the detection of human *myc* protein by immunofluorescence and western blot procedures.

Each vial of freeze dried anti-human *myc* contains enough affinity purified antibody to carry out 25 western blot procedures. When diluted according to instructions, the antibody concentration is 200 μ g/ml.

Performance tested antibodies which complement **oncor probes[™]** for oncogene research include:

Meteorite impacts on humans and on buildings

SIR—From nine years of observation with the Meteorite Observation and Recovery Project, a network of 60 cameras in western Canada, we have derived the frequency of meteorite falls on the Earth as a function of the total mass of meteorites to reach the ground for each event¹. Assuming that the total mass of an event is twice the mass of the largest fragment observed by the cameras, we conclude that

$$\log N = -0.689 \log m + 2.967$$

where N is the number of events per year in which a mass of at least m grams of meteorite is deposited in an area of 10^6 km^2 . This formula predicts 39 events per year with a mass of at least 100g in each million km^2 , or 5,800 such events on the total land area of the Earth.

Our present concern is to estimate the probability of persons or buildings being struck by meteorites. Our major assumptions are: (1) A human being occupies an area of 0.2 m^2 . (2) The smallest impact likely to be reported would involve a fragment of a few grams. (3) Typical meteorite falls consist of five major fragments. (4) Meteorite fragments larger than 200 g will normally penetrate a roof and ceiling. (We also assume that, if the total mass exceeds 500 g, each of the five fragments could penetrate a roof, whereas none of the pieces from lesser events will do so.) (5) Residents of North America spend 5 per cent of each day outside and 95 per cent of the day protected by a roof. (6) The total roof area of buildings averages 50 m^2 per member of population.

On the basis of these plausible assumptions we derive the frequency of impacts on people and on buildings and we wish to compare the values with recent experience. For this purpose we consider the population of the United States plus Canada (about 2.5×10^8 persons) since we expect news coverage of relatively minor events to be more complete for this sample than in many densely populated areas of the world. For this North American sample, our assumptions predict an annual rate of 0.0055 impacts on people (one event per 180 years) and 0.80 impacts per year causing damage to buildings.

The only documented case of a person being struck by a meteorite appears to be a fall on 30 November 1954². A fragment of a stony meteorite weighing 3.9 kg penetrated the roof and ceiling of a house in Sylacauga, Alabama, bounced off a large radio and struck a woman who was asleep on a couch, inflicting painful bruises. At first glance it would appear unlikely that there would be even one known event only 31 years ago, but the fact that there are no other verified cases elsewhere in the world indicates that impacts on people are extremely rare.

The prediction for impacts on buildings is more readily verified because the pre-

dicted rate is much higher. All known meteorite falls and chance recoveries are reported in the *Meteoritical Bulletin*, published about once per year in the journal *Meteoritics*. During the past 20 years, there are reports of 16 recoveries from fresh meteorite falls in the United States and Canada. For seven of these events, there was appreciable damage to some building, usually the roof of a home or garage. In the Louisville, Kentucky fall in January 1977, three separate buildings were struck, so there are nine reports of damage. Two other events, which we have not included, involved a small meteorite which caused no damage to a roof and a 1.3 kg object that damaged a mailbox. It is clear that impact on a building greatly increases the probability of recovery of the meteorite, since only a very small fraction of all falls will strike buildings, whereas half of the recent recoveries have such an involvement.

We would predict 16 damaged buildings in 20 years for this sample, which is close to the nine reports of damage. Since we would not expect small meteorites to be located, identified and reported in all cases, especially for minor damage to commercial buildings where there might be little interest in finding the cause of a leaky roof, we suppose the actual rate may be somewhat higher than our estimate. Our guess of five effective fragments per event may be too low.

To extrapolate to the entire world population, estimated at 5,000 million, then the number of events will increase by a factor of 20 over the North American sample if we use the same assumptions. One would then expect a person to be struck by a meteorite once in nine years and that sixteen buildings per year would receive some damage from meteorites.

We thank Dr Paul A. Feldman of the Herzberg Institute for valuable discussions.

A question of cellular immortality

SIR—In "Human T-lymphotropic retroviruses" (*Nature* **316**, 395-403; 1985), as well as other articles many authors now speak of the "immortalization" of cells by the expression of oncogenes. This term is generally used to refer to the ability of a cell line to grow *in vitro* indefinitely, without senescence or a growth crisis. The use of the term, to those not versed in the minutiae of oncogene nomenclature, would seem to imply specific gene(s) whose func-

tion is to prevent cell senescence. This gene would seem to have no corresponding physiological function *in vivo*, however.

A more plausible explanation would be that the cell, at a certain point in its step-wise differentiation, fails to turn off a regulatory gene. The cell continues to express this regulatory gene and the genes whose expression it controls. The cell is "stuck" in a state of expressing inappropriate genes and is prevented from terminal differentiation. This observation would fit with the fact that established cell lines, while not necessarily tumorigenic, require fewer steps to render them tumorigenic, perhaps as little as a growth factor with a specific effect on a certain differentiation state.

Weak violation — a new concept in relativity?

SIR—Quoting from *Nature News and Views*, "If there are violations of special relativity, they are at most weak violations, departures from what is not strict orthodoxy and not flat contradictions of it". Not everyone would agree with this statement. For many decades now, Einstein's relativity, and the need for absolute conformity with its basic tenets, have stood firmly in the way of any theoretical advance which dares to imply the slightest violation. But though it is improbable that we will ever see support for Marinov's claim, that the Earth's cosmic motion through space can be detected by tests confined to the laboratory, should this be demonstrated as proven, then Einstein's theory is violated by a death blow struck into its very heart.

Consistent with empirical data, a number of alternative laws of electrodynamics were shown by Clerk Maxwell to be derivable from a formula based on the relative velocity of interacting charges, taken in conjunction with what we would, today, term a "quantum electrodynamic" proposition (Fechner's hypothesis). Einstein's constraint, that any such law must satisfy the test of covariance, excludes a form of law which has recently been supported by experimental evidence from anomalous forces accompanying electric discharges in electrolytic solutions¹.

Consequently, research into practical applications of the indicated law has, at least until the present time, been retarded, blocked by the "inviolable" principle of relativity, and for the very reason that a successful outcome would be a strong violation and therefore improbable.

Whereas Marinov has sought to chal-

lenge Einstein directly on the speed of light issue, the Achilles' heel may already have been exposed in the application of electrodynamic law to electrochemical processes. Relativity, in its classical sense, will undoubtedly survive, but the real question is whether the test of time will continue to support Einstein's requirement that each and every relatively-moving observer constitutes his own personal reference frame for the locally-applicable laws of physics.

Structure and activity of barbiturates

SIR—It has long been a puzzle that caffeine and other purines should be stimulants while the chemically similar barbiturates are sedatives¹. I suggest that the latter are no longer planar in solution, being hydrated to the *gem*-diols and having the molecule folded about its principal axis (boat configuration).

Hydration of the central carbonyl can reasonably be expected because of the high positive charge on each of the neighbouring amide nitrogens. The result of electron-withdrawal near a carbonyl group is most familiar as chloral hydrate. Such *gem*-diols are known to catalyse the hydration of carbon dioxide, if the pH is high enough for partial ionization of the diol². Most barbiturates would then be fully ionized as amides, unless they were substituted at both nitrogens. Veronal, therefore, should be inactive, and etorbarbital active, in promoting the hydration of dissolved carbon dioxide to carbonate.

As for biological activity, *gem*-diols are ideally constituted to bind the ionized carboxyl of GABA and other amino acids.

Linking impacts and plant extinctions

SIR—The discovery of shock-metamorphosed quartz grains¹, in addition to earlier evidence from siderophile enhancements² and microtektite-like spheroids³⁻⁵ appears to confirm the existence of a bolide event at the Cretaceous-Tertiary (K/T) boundary, but a causal connection between this event and the extinctions of many plants and animals remains in dispute. The pattern of extinctions in the marine realm⁶⁻¹⁰ generally conforms to

the hypothesized effects of an asteroid impact, but evidence from the terrestrial biota has been somewhat paradoxical. Though the situation for land animals remains equivocal (because some of their fossils are suspected to have been reworked), recent evidence collected from both fossil pollen and palaeosols appears to support the marine data for a sudden, catastrophic change at the K/T boundary.

Latest Cretaceous pollen sequences recovered from many sites in Montana^{11,12}, Colorado¹³ and New Mexico¹³ display dramatic shifts in the ratio of fern spores to angiosperm pollen at the K/T boundary. These widespread palynofloral disruptions suggest that the terrestrial flora suffered a profound ecological shock at the boundary, and the close proximity of these pollen breaks to Ir anomalies and highly shocked quartz grains implicate an asteroid impact. The pattern of plant destruction and renewal is similar to that observed at Tunguska¹⁴, Krakatau¹² and Mount St Helens¹⁵. Initial devastation might have been produced by the shockwave¹⁶ that would have resulted from a terrestrial impact¹⁷.

In addition, information collected from palaeosols (M.D.S. and G.J.R., unpublished data) in Montana tends to support the pollen evidence for a change in the flora at the K/T boundary. Palaeosols from the Hell Creek Formation are well developed, weakly calcareous and have a microstructure indicative of warm, oxidizing conditions. These Cretaceous palaeosols combined with pollen data are suggestive of a well drained closed-canopy forest of subtropical aspect, dominated by broadleaf angiosperms. Mean annual rainfall was subhumid, but periodic, possibly monsoonal. The presence of mummified dinosaur corpses, as well as "growth rings" in the teeth of some endothermic vertebrates¹⁸, provides evidence for seasonally dry conditions. By contrast the palaeosols of the Tullock formation have a weak microstructure, and tend to be poorly developed with thick organic layers and abundant siderite nodules, suggestive of a cooler climate and poor drainage. In combination with pollen data these palaeosols are indicative of a temperate flora dominated by conifers and situated in a swamp environment. A modern analogue would be bald cypress swamps that presently exist over portions of southeastern North America. Coals are thicker and better developed in the Tullock formations, consistent with the hypothesized existence of poorly drained, widespread wetlands.

The change in palaeosols is abrupt and occurs directly above the pollen break at the K/T boundary, although it is difficult to say how sudden the palaeosol change was because of a complex erosional hiatus at the boundary. The palaeosol change is generally consistent with an interpretation made by Smit and van der Kaars¹⁹ for palaeochannels in the Bug Creek area.

Evidence from both pollen and palaeosols suggest a change across the boundary to unstable conditions in the early Palaeocene, shown by channel downcutting and followed by the establishment of a new geomorphic equilibrium. Long-term palaeosol and pollen changes are compatible with base-level adjustments, possibly related to a drop, then a rise in sea level. The synchronous occurrence of an Ir anomaly, spheroids, pollen breaks and shocked quartz at the boundary is suggestive of an additional catastrophic destabilization.

The presence of abundant palaeosols places constraints on the degree of resorting of fossils within the Hell Creek Formation. For example, it has been suggested²⁰ that nearly all fossil material contained in the Hell Creek faunal-facies was reworked and transported. This is an overstatement, as palaeosols would be destroyed in frequently disturbed environments, and the widespread occurrence of palaeosols in association with large fossils (less commonly with microfossils) suggests that much, if not most of this facies was formed in place. The truncation and strong development of palaeosols at the K/T boundary, together with the lack of palaeosols associated with fossils of the Bug Creek faunal-facies is consistent with the suggestion¹⁹ that some of these fossils were transported.

A more detailed picture of the Hell Creek-Tullock palaeoecological transition awaits further analysis of data. We believe, however, that at the moment the asteroid impact hypothesis provides the most parsimonious explanation for changes in plant communities across the K/T boundary.

THE DEVELOPMENT OF A MEDICINE

R. B. SMITH

A highly readable account of an area which is of vital interest to the medical profession and the public alike

The Development of a Medicine places the discovery and development of medicines in a historical context and then explains the extremely complex and lengthy process by which a drug or medicine is developed from the laboratory bench to availability for prescription by the physician.

After twenty years' research and clinical work in medicine and pharmacology, R. B. Smith is now a consultant to the pharmaceutical industry.

CURRENT EUROPEAN ANAESTHESIOLOGY, Volume 1, 1985: The Yearbook of the European Academy of Anaesthesiology

edited by **R.M. Jones**, *Guy's Hospital Medical School, London*

A greater awareness amongst clinical researchers throughout Europe can only enhance the more appropriate direction of resources towards safer patient management. The Academy's Yearbook is intended to help achieve this goal by presenting summaries of papers published in relevant European journals. The summaries are grouped under the subject headings of pharmacology, clinical practice, equipment and monitoring, medical problems, and resuscitation and intensive care. Each summary will be reviewed by an acknowledged authority in the subject who will evaluate the paper's clinical significance and its applicability to contemporary practice.

PAEDIATRIC PERSPECTIVES ON EPILEPSY

edited by **E. Ross**, *Charing Cross Hospital, London* and
E. Reynolds, *King's College Hospital, London*

The subject of paediatric epilepsy is now attracting considerable interest among researchers and clinicians, and this book presents the latest research findings resulting from intensive epidemiological, immunological and neuro-investigatory studies. Paediatricians, neurologists and all involved in the practical care of children with epilepsy, will find this book a major step forward in their understanding of the diagnostic, aetiological, therapeutic, prognostic and social aspects of the subject.

HEAD AND SPINE IMAGING

edited by **C.F. Gonzalez**, *Thomas Jefferson University Hospital, Philadelphia, Pennsylvania*, **C.B. Grossman**, *Methodist Hospital Graduate Medical Center, Indianapolis, Indiana* and **J.C. Masdeu**, *Albert Einstein College of Medicine, Montefiore Hospital and Medical Center, New York*

This is a definitive reference/atlas of head, neck and spine imaging. Lavishly illustrated with examples of all imaging modalities, it gives special emphasis to the newest advances in NMR. It is the most complete and comprehensive work presently available on the topic.

0471 89747 7 966pp February '85 £154.00

THEORETICAL EPIDEMIOLOGY: Principles of Occurrence Research in Medicine

by **O.S. Miettinen**, *School of Public Health, Boston, Massachusetts*

This text treats theoretical epidemiology as the discipline of how to study the occurrence of phenomena of interest in the health field. It delineates major principles of study design and data analysis in research into the frequency of occurrence of illness and related phenomena in human populations whether in the community or in clinical situations. Thus it is concerned with the principles of the dominant type of research in applied medical science and in health care administration.

HEAD AND NECK CANCER

edited by **R.E. Wittes**, *National Cancer Institute, Bethesda, Maryland, USA*

Tumours of the head and neck are amongst the most difficult to diagnose and manage. Particularly important in this group are tumours affecting the brain. This book discusses the recent rapid advances in diagnosis which have occurred as a result of new imaging modalities. Surgical, radiological and chemo-therapeutic treatments are still the mainstay of management but novel methods of treatment are being introduced, such as hyperthermia for certain facial and oral tumours and the targeting of cytotoxic drugs by the use of monoclonal antibodies in, for example, lymphomatous tumours of the neck and oesophagus.

PEDIATRIC NEUROSONOGRAPHY: Clinical, Tomographic and Neuropathologic Correlates

by **A.W. Fischer**, *Medical College of Georgia*, **J.C. Anderson**, **R.M. Shuman** and **W. Stinson**, *all of the University of Nebraska Medical Center*

This text serves as an introduction to cranial sonography, providing viewpoints from specialists in the fields of neurology, neuropathology, and radiology. It illustrates the extended use of sonography for pediatric neurologic diagnosis beyond the neonatal period and deals with the frontiers of sonographic recognition of neurologic disease. Focusing on normal and developmental anatomy, *Neurosonography* covers ultrasound physics, instrumentation, scanning techniques, brain anatomy and development, and assorted acquired and congenital abnormalities.

0471 89252 1 286pp October '85 £46.00

THE PRACTICE OF ECHOCARDIOGRAPHY

edited by **R. Kraus**, *University of California, Los Angeles School of Medicine*

The Practice of Echocardiography provides a complete, up-to-date discussion of all aspects of clinical echocardiography. Noted authorities in this field have contributed chapters on such topics as physics, instrumentation, techniques, M-mode and two-dimensional echocardiography and the new advances in Doppler and hand-held two-dimensional instrumentation.

Fall out over atomic tests

John Simpson

Fields of Thunder: Testing Britain's Bomb. By D. Blakeway and S. Lloyd-Roberts. Allen & Unwin:1985. Pp.243. Hbk £10.95; pbk £3.95.

Clouds of Deceit. By J. Smith. Faber & Faber:1985. Pp.174. Hbk £8.95; pbk £4.95.

A History of British Atomic Tests in Australia. By J.L. Symonds. Australian Government Publishing Service:1985. Pp.593. A\$28.

Just Testing. By D. Robinson. Collins/Harvill:1985. Pp.595. pbk £5.95.

In January 1985 a unique event occurred. A foreign judicial commission came to Britain to cross-examine current and former scientific civil servants about events thirty years ago classified as military secrets, but now released. The investigations of this Australian Royal Commission into the short and long term consequences of British nuclear testing in Australia took place at a time of growing concern that participants in nuclear weapon tests in the atmosphere were more susceptible in later life to cancer, and certain other diseases, than the rest of the population. This concern was heightened by the attempts of those who had fallen ill to gain compensation for their suffering, disabilities and possible premature death from their parent governments; the refusal of certain of those governments to admit liability, and the organization of pressure groups to assemble evidence to demonstrate liability and to lobby for changes in compensation rules. It was against this background, including the publication next month in Australia of the Report of the Royal Commission, that these four books were written and can be evaluated.

Several obvious distinctions can be made between the books. Symonds was commissioned to write by the Australian Department of Resources and Energy as a person who held an official position in the Australian Atomic Energy Organization, and had privileged access to Australian and British documents whereas the other three are written by professional journalists and writers. It should therefore be no surprise that the theme of Symonds' work is that no unexpected events or irresponsible actions of states, scientists or officials occurred and, equally unsurprising, that the other three books appear to start from the assumption, fostered by long standing governmental secrecy, that there are human and state culpability and errors to be exposed when investigating British nuclear testing activities. Symonds' implicit conclusion is thus that there is little to be concerned about as a consequence of the tests, whereas the overt conclusion of the other three writers is the exact opposite.

There are other differences in the coverage. Smith and Symonds only cover events in Australia, while Blakeway/Lloyd-Roberts and Robinson deal with all

the British atmospheric nuclear tests, including those at Christmas Island. Symonds writes a simple chronology of events, using only government documents, while Blakeway/Lloyd-Roberts and Smith use historical sections, based upon Royal Commission documents and hearings, interviews with people involved in the tests and newspaper reports to argue a particular thesis.

Blakeway/Lloyd-Roberts argue that governments should now acknowledge that some, though not all, test veterans suffered as a consequence of the tests, whereas Smith presents a pot-pourri of accusations that the British media were subservient to the government of the day (an unsurprising view given her personal difficulties in having stories on nuclear testing published in the *Sunday Times*) and the need for nuclear disarmament and support for the test veterans against their parent governments. By contrast, half of Robinson's book consists of interview material gathered from servicemen involved in the tests. He attempts to view events from the perspective of the men rather than their commanders.

The literary style and presentation used in the volumes also differs appreciably. Symonds uses camera-ready copy, has appendices after most chapters in which important documents are reproduced and has a curious system of references to the side of the text. There are also elements of

repetition in the text. It is thus essentially an extended, detailed and exhaustive report, rather than a commercially produced book and its structure does not make for easy reading. Yet as a work of reference, it contains much more documented information than any of the other volumes.

Robinson, in half his book, uses an impressive technique of short quotations drawn from interviews with people who participated in the tests juxtaposed either on the basis of topics (for example eating facilities on Christmas Island) or experiences of specific tests. These quotations are interspersed with brief medical histories of each new individual introduced into the book. The technique gives a sense of what it was like to be there, of the ignorance of what was happening felt by those who were taking part and the way in which rumours about events spread.

The Blakeway/Lloyd-Roberts work is the more polished of the other two books, offering both greater detail and wider coverage than Smith. It is also the only one of the four with an index. It contains a number of glaring factual errors, however (e.g. on page 153 a bomb is dropped from an aircraft at 13,000 feet and explodes at 15,000 feet) and also is guilty of misrepresenting the proposals made in the mid-1950s to hold tests of initiator devices for nuclear weapons in Scotland. Thus on page 159 in a passage about the Christmas Island hydrogen weapon tests we are told that "the decision was bred from the same scientific confidence and political expediency that produced the idea that tests should take place over mainland Britain" yet the massive difference in the nature of the two types of tests is conveniently ignored.

In addition, when these authors find themselves confronted by lack of information, they occasionally resort to what can only be described as smear tactics. For example (page 177) "there is no indisputable evidence that large numbers of men

Britain's second atomic test at Woomera rocket base in Australia in January 1954 — watched here by Sir William Penny who led the team carrying out the tests.

at Christmas Island were unknowingly exposed to radiation" yet later in the same paragraph we are told "the hydrogen bomb tests were administered and carried out by the same authorities responsible for the Australian tests, and there is no reason to believe that the safety precautions changed for the better once the move had been made to the central Pacific". Similar remarks, however, could be made about all the books other than that of Symonds on the grounds that none of them has accurately reproduced the listing of UK atmospheric tests and their yields published by the Ministry of Defence in 1984.

Because three of the books draw on much the same body of information for their accounts of events, the main differences are in their perspective upon and interpretation of history, rather than any revelations about what happened. Yet a number of issues of substance do emerge. One is the crude techniques used for specifying the requirements for the initial test sites (the use of a map to see how far the nearest large town was from the US Nevada site and adding a safety margin). Another was the error of exploding the first device in the 1953 test series at a time when the meteorological conditions were unsuitable and the disputed consequences of this for both aborigines and the aircrew sent to tackle the resultant nuclear cloud.

Further issues include the degree to which procedures laid down for radiation safety were actually complied with; the extent to which aboriginal intrusions into the Maralinga test site went unreported in official documents; the degree to which unjustified risks of exposing personnel to radiation were taken in pushing the British nuclear weapon programme through to fruition in six years and finally, there was the impact of war-time agreements with Canada and the United States on the relationship between the United Kingdom and Australia.

One unresolved issue remains central to all these works: what assumptions can be made about the relationship between exposure to nuclear radiation, especially at low levels, and ill health and premature death. The official view remains that threshold values can be established to distinguish between those who are "safe" and those at risk. Opponents argue against this, largely on the grounds of statistical correlations. The neutral reader is likely to remain unconvinced either way on this issue by reading any of these books, but they will no doubt provide additional ammunition for a controversy with profound human, scientific and political dimensions which seems likely to continue indefinitely. □

John Simpson is Senior Lecturer in the Department of Politics, University of Southampton, Southampton SO9 5NH, UK. A second edition of his book, The Independent Nuclear State: The United States, Britain and the Military Atom, will be published next year by Macmillan, London.

The ups and downs of an antibiotic

Trevor I. Williams

Penicillin: Meeting the Challenge. By Gladys L. Hobby. Yale University Press: 1985. Pp. 319. \$30, £30.

THE timing of the events surrounding the appearance of penicillin is well-established. It was discovered by Alexander Fleming in 1928 and the crucial research demonstrating its remarkable therapeutic potential was carried out by Howard Florey, Ernst Chain, and a small group of colleagues at Oxford between 1939 and 1941, with large-scale production being established in the United States by 1944. In 1945 Fleming, Florey and Chain shared the Nobel Prize for Physiology or Medicine. Although there remained much to be learnt about penicillin, the peak effectively was passed forty years ago. It is surprising, therefore, that interest in the history of penicillin has lately intensified and still remains controversial. Since 1979 there have appeared an important new biography of Fleming; two official biographies of Florey; and an official biography of Chain is shortly to be published.

It might be supposed, therefore, that there would be little room for yet further work on the history of penicillin. This book by Gladys Hobby is different, however, in that it is a comprehensive and well documented review of penicillin as a drug and thus largely avoids the problems of personality that are likely to beset biographers.

The treatment is not wholly objective, however and, like others before her, Dr Hobby explores the problem of why Fleming not only failed to develop penicillin himself but quickly lost interest in it. She is surely right in supporting the view that a change in the climate of medical opinion was a significant factor. In 1928, there was much scepticism about the potential of chemotherapy, especially in St Mary's Hospital, which was strongly orientated towards vaccine therapy under Almroth Wright. By 1939, however, the demonstrable success of the sulphonamides had changed the attitudes of many people very considerably.

In commenting on Fleming's own plea that he failed through lack of technical support she makes one very curious statement. She attributes to Chain a comment "that without partition and paper chromatography, infrared and ultraviolet spectroscopy, nuclear magnetic resonance and electronic spin resonance — techniques not known in the 1920s and early 1930s — isolation of an unstable natural product such as penicillin would have been exceedingly difficult". It is hard to believe that Chain ever made such a statement,

for none of these techniques played any part in the original purification of penicillin for clinical trial. A possible explanation is that the author is confusing the isolation of penicillin with much later work on the chemical structure of penicillin to which, with an account of semi-synthetic penicillins, some 20 pages are devoted.

The first part of this book adds little to the description and interpretation of events in the UK save that it puts in better perspective the fundamental importance of N.G. Heatley's contribution to both the assay of penicillin and its extraction from crude culture medium. Its real strength lies in the second part, which deals with the development of penicillin in the United States after the visit by Florey and Heatley in the summer of 1941 to enlist the support of the American pharmaceutical industry. We are rightly reminded that even before that visit there had been some sporadic interest there in the phenomenon of antibiosis in general — Merck, for example, had supported S.A. Waksman at Rutgers University since 1939 — and penicillin in particular.

Dr Hobby herself, with M.H. Dawson and Karl Meyer at the College of Physicians and Surgeons in New York, experimented with crude penicillin very shortly after the publication of the first paper by the Oxford group in the *Lancet* of 24 August 1940. In 1944 she joined the pharmaceutical firm Pfizer as a microbiologist and is thus well qualified to recount the history of industrial production of penicillin in the USA. She also deals briefly with production in Canada, Holland, France, Germany and Japan. She brings out very clearly the dilemma of the American pharmaceutical industry during those critical years: heavy investment in fermentation plant might be rendered worthless almost overnight if the chemists came up with a viable synthesis — which in the event they did not.

One controversial issue is evaded, namely that process patents taken out by the US industry led to allegations in the UK Parliament and elsewhere that penicillin had been 'stolen' from Britain. Although these allegations were effectively disproved in a detailed inquiry initiated by Vannevar Bush in 1952, echoes of them are still heard. The overwhelming contribution of the USA to industrial production has encouraged popular belief there that penicillin was for all practical purposes an American discovery. Dr Hobby is at pains to dispel the illusion: "... penicillin was a British discovery — it was discovered in England, first studied in England, first used clinically in England — and it probably was one of Britain's major wartime contributions to society". □

Dr Trevor I. Williams, 20 Blenheim Drive, Oxford OX2 8DG, is editor of Endeavour. He worked in the Sir William Dunn School of Pathology, Oxford, 1942–5 and his biography 'Florey: Penicillin and After' was published by Oxford University Press in 1984.

Qwiffs and quantum leaps

Brian D. Josephson

Mind and the New Physics*. By Fred Alan Wolf. Heinemann: 1985. Pp. 342. £14.95.

IN THIS book the author expounds his ideas relating to a postulated connection between quantum mechanics and mind, a connection which is now beginning to be recognized as being possibly important by a number of scientists. Wolf starts from the conventional point of view that the quantum-mechanical wave function (or "qwiff" in his terminology) represents the potential for anything physical to become manifest, and regards the process of making decisions as one of interaction with the (potential) future. He postulates that we have control over the future by deciding what to observe, and thus determining which way the wave function should collapse. We capture possibilities by observing them and collapsing the wave function appropriately in the same way that a fisherman captures fish in his net. The author additionally discusses in a rather metaphorical way some information-processing aspects of quantum theory, as well as a large number of other, on the whole rather more questionable, ideas.

While the putative mechanism for being able to control the future has a certain degree of plausibility, conventional quantum theory would argue that the chance of *not* finding a particular possibility of interest should be taken into account as well as the one of actually finding it, these two possible outcomes being associated with wave function collapses in different directions. This would seem to lead to theoretical predictions distinctly different from those proposed by Wolf. His process for modifying the outcome would work only if a differential collapse mechanism were in operation, and would make the theory very close to E.H. Walker's theory of the control of physical reality by the will which was published in Vol. 3 of *Psychoenergetic Systems* (1979).

Unfortunately, the kind of attention to detail and use of logical methods of argument that might have made the author aware of matters such as the discrepancy between the mechanism he proposes and conventional theory is not a feature of this book. Its basic structure is one of informal expositions of standard theory, followed up by intuitions about their meaning in the author's scheme of things. Despite my sympathy with what Wolf is trying to do, it seems to me that the connections proposed, while occasionally being significant, have been arrived at mainly by a process of coupling together any two en-

ties that have some nebulous resemblance to each other (a typical example is the connection between Bose-Einstein statistics and love, discussed on pp. 152-154).

One can have little more confidence in the mathematical parts of the book, the illustrations for which have been produced using a computer apparently lacking graphics facilities, which hardly makes them easier to follow. Starting with an elementary howler in the example given to illustrate the addition of two wave functions on p. 191, which might be excused as a momentary lapse of attention, the author goes on to describe the equation $\langle 1/I \rangle = 1$ as representing the law "The Mind is One". He then proceeds further to equations supposedly representing the characteristics of Enterprise, God and Satan, at which point the book starts to bear a distinct resemblance to some of the more dubious offerings from the public that arrive occasionally in one's mail box. It could be that there is some sense behind these strings of equations, but unfortunately Wolf does not consider it important to go into the details so that the critical reader can judge for himself.

The side effect of books such as this may be to cause other books and journal articles, which treat this subject in a more serious manner, to miss the attention they deserve. There come to mind Rupert Sheldrake's *A New Science of Life*, which has been criticized mainly on account of its unorthodoxy and not because of any errors or inconsistencies in its arguments; Fritjof Capra's *Tao of Physics*; D. Bohm and B.J. Hiley's article (*Fdn Phys. USA* **14**, 255-274; 1984) which indicated that mind-like characteristics of nature may be inherent in the equations of quantum physics; and the two papers of H.P. Stapp (*Fdn Phys. USA* **12**, 363-399; 1982 and **15**, 35-47; 1985) on the connection between mind, matter and quantum mechanics. On the assumption that important new ideas may in fact be buried in Wolf's book, one must hope that a subsequent, more rigorous account will be written, directed at the scientist rather than at the non-scientist who seems to be the target of this one.

Brian D. Josephson is Professor of Physics in the Cavendish Laboratory, University of Cambridge, Madingley Road, Cambridge CB3 0HF, UK.

Taking an aim

Gregory Gregoriadis

Red Blood Cells as Carriers for Drugs. Edited by J.R. DeLoach and U. Sprandel. Karger: 1985. Pp. 162. DM 125, \$44.25.

THE development of carriers to obtain optimal release of drugs where they are needed, and protection from hostile environments or premature loss, is a subject of growing interest and a hopeful bet in biotechnology ventures. Currently popular carriers include antibodies, polymers, liposomes and other colloids. With only a minority of workers favouring erythrocytes, what then is so special about them to warrant a meeting and a book? Several things according to the editors and the contributors. Most medical researchers are familiar with erythrocytes, a known quantity to be trusted, by clinicians especially (the danger of unwanted contaminants in other people's blood, is avoided by using the patient's own erythrocytes).

Erythrocytes can, in theory at least, optimize drug action in more than one way. For instance, they end up sooner or later in the reticuloendothelial system which is associated with a large number of microbial and other diseases, and could therefore carry drugs there. This aspect is discussed in chapters on the use of cells loaded with metal chelators which facilitate removal of stored iron, or with hydrolytic enzymes which can break down stored substrates in the tissues of patients with storage diseases. Further, (human) erythrocytes have a life span of over 100 days, an important feature for slow re-

lease of drugs into the circulation

The book describes experiences with the release of antimicrobial and anticancer drugs from circulating erythrocytes. Inactivation of toxic metabolites entering erythrocytes by enzymes which have been introduced into the cells is discussed in chapters on asparaginase, rhodanese (co-entrapped with sodium thiosulphate for cyanide detoxification), or urate oxidase-containing erythrocytes. Other applications include erythrocyte-mediated introduction of DNA and antibodies into eukaryotic cells and the enrichment of erythrocytes with allosteric effectors of haemoglobin or with 6-phosphate dehydrogenase.

Is this all too good to be true? Unfortunately yes. The editors and some of the authors recognize the formidable problems with the proposed uses, especially in terms of wide acceptability. For instance, there are already a number of simple and safe man-made carriers which can deliver drugs to the reticuloendothelial system efficiently. Further, release of drugs from circulating cells at a constant rate will probably be impossible to achieve. Perhaps the greatest advantage of erythrocytes over other systems is their long circulation time and their use in detoxification looks realistic enough. The book, discussing most aspects of the erythrocyte carrier and related technology in 19 short chapters, is the first one devoted entirely to this system and should prove useful to those interested in drug delivery.

Gregory Gregoriadis is Head, Medical Research Council Group, Academic Department of Medicine, Royal Free Hospital School of Medicine, London NW3 2QG, UK.

Putting flesh to the phantoms

Graham Burton & D.D.M. Wayner

Free Radicals in Biology and Medicine. By Barry Halliwell and John M.C. Gutteridge. Clarendon: 1985. Pp.346. £30, \$45.

THE transitory nature of free radicals, conferred on them by an unpaired valence electron, has made direct proof of their involvement in a chemical reaction a challenging task. This is especially so within the complex web of chemistry associated with biological systems. Nevertheless, there is now strong, albeit indirect, evidence that free radicals are involved in at least some normal and abnormal cellular processes, including, for example, photosynthesis, inflammation, cancer and toxic reactions to some drugs and pesticides. Research interest in free radicals in biology and medicine has now grown to the extent that there are entire conferences and journals devoted to the subject.

Anyone wishing to gain an appreciation of the state of knowledge in this diverse, interdisciplinary field, together with a feel for the difficulties involved in pinpointing the *in vivo* involvement of radicals, will welcome the arrival of this very readable book. Furthermore, the authors have realized that further progress will require

a better understanding of the chemistry of free radicals. Accordingly, they have made accommodations in the text and included an appendix on bonding and atomic structure to help those readers who lack the necessary background. However, the chemically naive may find the number of chemical reactions and structures daunting (and will not be helped by errors in the printed structures of some chemical intermediates).

More importantly, the speculative nature of some of the reaction schemes is not always indicated. For example, two mechanisms are presented for the trapping of the superoxide ion by the antioxidant vitamin E (p.62 and p.173); not only are they contradictory, but both seem unlikely because they involve electron and proton transfers which have never been demonstrated experimentally and are improbable on thermodynamic and kinetic grounds. A more likely possibility is that the small amount of the more reactive hydroperoxyl radical that is in equilibrium with superoxide ion at physiological pH will rapidly abstract a hydrogen atom from vitamin E, as is found to occur with other peroxy radicals.

Reflecting the thrust of much of the research in this field, the authors devote considerable space to the potential roles played by the superoxide ion, hydrogen peroxide, the hydroxyl radical, iron and other transition metals, and the enzymes superoxide dismutase, catalase and glutathione peroxidase. They also describe the complex interplay of enzyme systems and the importance of maintaining sufficient concentrations of cofactors such as reduced glutathione and NADH. The reader, however, is left with the impression that the very reactive hydroxyl radical is the primary agent of destruction; this may be true, but it is also important to realize that the chain-carrying peroxy radicals (which will almost certainly form as a result of hydroxyl radical attack on neighbouring molecules) can lead to a much larger increase in the initial damage. In this case, other antioxidant systems (for example vitamin E, vitamin C) become important.

There is no direct referencing within the body of the text (except where individual researchers are named) but each chapter is supplemented with an alphabetical list of selected references (up to and including 1984) for further reading. This system has its advantages, but will frustrate those pursuing specific points in the text.

Although the book is aimed at biologists and clinicians, it is a good starting point for anyone wishing to get a clear introduction to current aspects of free radical research in biology and medicine. It should, therefore, be of wide appeal. □

Graham Burton is an Associate Research Officer and D.D.M. Wayner a Research Associate in the Chemistry Division, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ontario K1A 0R6, Canada.

Adding up parts of the past

I Grattan-Guinness

A History of Algebra from al-Khwārizmī to Emmy Noether. By B.L. van der Waerden. Springer 1985; Pp.271. DM 98, \$34.50.

ALGEBRA has long been a major component of mathematics, and so has attracted a good deal of interest among historians. This book occupies a special place, for its author has been one of the most distinguished algebraists of our century. After a chapter on medieval Muslim contributions, he takes the story through Renaissance Italy to Descartes, and then on to the algebraic structures that became a 19th-century concern: the work of Gauss and Galois, then the development of group theory, and the various algebraic systems which culminated in a sort of synthesis with van der Waerden's teacher, Noether.

As algebra has already been studied by many other historians, several parts of this book cover familiar ground: its novelties are drawn from recent research by others on various historical figures, which is used heavily and with full acknowledgement. While no major recasting of the history is thereby caused, the new details are very welcome. However, when one considers the interaction between algebra and other branches of mathematics, gaps in the story do emerge, which neither this nor other histories properly fills. I shall mention two.

One of the chief links for algebra has been with calculus, and its uses in applied mathematics. Indeed, a major issue there at times from the mid 18th century onwards was the possibility of securing some of these topics entirely within certain algebraic theories. While these attempts were successful, some important consequences followed for algebra: for example, they led to the early stages of functional equations and differential operators, the first theories in algebra explicitly divorced from interpretations in terms of length and number.

Partly as a result of these attempts, the 19th century saw the introduction of a variety of algebras in which laws other than the usual ones, suggested by arithmetic, were satisfied. For some reason the English became especially attracted to such studies, which gained collective prominence in their time, both in England and to some extent abroad. It is therefore rather astonishing that van der Waerden deals only with Hamilton, and that his book is completely silent on Babbage, Boole, Gregory, Herschel, De Morgan and Sylvester. The history of the history of algebra still has much life left in it. □

TADPOLE by TH Caradoc-Davies

TADPOLE is a general purpose numeric database management program with a built-in statistics package. It runs on the IBM PC with one or two disk drives and on the IBM XT. It is easy to use and has a detailed instruction manual.

Data files can be created and edited, each consisting of up to 9999 records. Each record can have up to 60 fields of data and each field is a number of up to six digits.

Data files can be up to 320 kbytes in size on a floppy disk system and much larger on a hard disk system.

Statistical tests available in TADPOLE are:

Descriptive: Means, standard errors, skewness, kurtosis, minimum value/maximum value plus range, median, frequency analysis including bar charts.

Parametric: Student's *t* test for paired and unpaired data, correlation coefficient, linear regression, multiple linear regression, ANOVA one way and two way for equal and unequal groups.

Non-parametric: Contingency tables, chi-squared 2 x 2 and N x K, Fisher's exact test, McNemar's test for the significance of change, one sample chi squared test, Mann Whitney U test, Wilcoxon signed ranks matched pairs test, Spearman's rank correlation test, Kendall's rank correlation coefficient, Kendall's coefficient of concordance, Kruskal-Wallis one way analysis of variance and Friedman's two way analysis of variance by ranks.

The TADPOLE manual contains explanations of all the statistical procedures used, together with guidance on when a particular test is appropriate. To complement the explanations, the manual also contains examples and exercises on the different procedures.

Package includes:

Manual and 5.25" floppy disk for the IBM PC

BIOISOFT
Leaders in biomedical software
ANNOUNCE

STATSTREAM by A Bangham

STATSTREAM has at its heart a library of 76 procedures including data entry, graphing, text-windowing, statistical tests, function-fitting etc. These can be used very simply by:

- (1) Calling the helpful menu driven Statpack, which enables a variety of parametric and non-parametric tests to be done, after a single entry of data.
- (2) Using the 32 demonstration programs designed to teach the user all about statistics and fitting functions to data.
- (3) Writing straightforward BASIC programs to incorporate the desired procedures.

STATSTREAM is usable by, and useful for, everyone from the beginner, new to statistics and computing, to the professional statistician or research worker who wishes to incorporate the elegant STATSTREAM procedures in his own BASIC programs. It is also a first class educational tool.

Package includes:

Two packed 5.25" floppy disks for the Apple II series (3.3 DOs, min 48k RAM) (which can be used with one or two drives) plus a comprehensive manual.

EXPERT 4 by Rivers

An easy-to-use sophisticated disk-based 'Expert System' development tool for the IBM PC at an incredibly low cost.

EXPERT4 can be used to create and manipulate a knowledge base, which employs models of human reasoning or 'artificial intelligence'. It draws on deductive and fuzzy logic, multidimensional statistics and cognitive psychology. The theory behind EXPERT4 is fully discussed in the documentation which accompanies the disk.

EXPERT4 offers a spreadsheet which enables the user to create files or 'domains' each of which is made up of 'elements' which have 'attributes'. These have 'attribute values'. For example, in a domain called 'People', 'Jane' is an element. One of her attributes is 'Hair colour'. Jane has brown hair hence

'Brown' is the attribute value.

Inferencing facilities in EXPERT4 calculate and display relationships amongst the elements and attributes in terms of similarity and typicality. Any two selected items can be compared in detail for their similarity and differences. An example use would be to assist with diagnosis of a group of diseases with similar symptoms.

Other potential uses of EXPERT4 are manifold, but to give the user an introduction to the program, two completed domains are incorporated on disk as examples.

Package includes:

Documentation + 5 1/4" floppy disk for the IBM PC.

NUTRITION AND IMMUNITY

M.E. Gershwin, R.S. Beach and L.S. Hurley
1985, 432pp., \$58.00/£49.00 (UK only), ISBN: 0.12.281450.9

FROM THE PREFACE: The relationship between nutrition and immune function is gaining increased prominence and reflects a major expansion of both field and wet bench research. There is a growing realization that nutrition may influence immune function not only in populations with severe malnutrition and a high incidence of infectious disease, but more importantly in populations with relatively mild or single nutrient deficiencies.

IMMUNOLOGICAL METHODS

Volume III

Edited by **I. Lefkovitz and B. Pernis**
1985, 496pp., \$54.50/£48.50 (UK only), ISBN: 0.12.442703.0

Contents include: Methods in Molecular Immunology: Chromosomal Walking in the Major Histocompatibility Complex. DNA-Mediated Transformation of Lymphoid Cells. Cloning of cDNAs with Vectors Permitting Expression in Host Cells. Construction of Vectors for Immunoglobulin Reverse Genetics. Strategies of Oligonucleotide Synthesis.

AN ATLAS OF IMMUNOFLUORESCENCE IN CULTURED CELLS

M.C. Willingham and I. Pastan
1985, 208pp., \$35.00/£30.50 (UK only), ISBN: 0.12.757030.6

Multiple examples of the images produced by fluorescently labeled antibodies bound to different cellular proteins have been compiled in this important work. The patterns from a variety of organelles and cell structures are represented, giving researchers a broad outline for the utilization and interpretation of fluorescence images. The authors discuss the methodology of immunofluorescence, then present examples of fluorescence patterns in cell surface membrane structures, cytoskeletal structures, and cytoplasmic organelles.

Susan Van Noorden and Julia M. Polak. The gold method as applied to lectin cytochemistry in transmission and scanning electron microscopy. Marc Horisberger. The enzyme-gold technique: a new cytochemical approach for the ultrastructural localisation of macromolecules. Moise Bendayan. Colloidal gold and colloidal silver - metallic markers for light microscopical histochemistry. John M. Lucocq and Jürgen Roth.

MONOCLONAL ANTIBODIES FOR CANCER DETECTION AND THERAPY

Edited by R.W. Baldwin and V. S. Byers

1985, 416pp., \$34.95/£29.00 (UK only), ISBN: 0.12.077021.0 Pbk
1985, 416pp., \$65.00/£56.50 (UK only), ISBN: 0.12.077020.2 Hbk

This volume appraises the status of clinical studies in which radioactive isotope labelled monoclonal antibodies are being used to detect human cancer by gamma camera imaging. The implications for the development of methods for targeting therapeutic agents are also considered.

THEORIES AND MODELS IN CELLULAR TRANSFORMATION

Edited by L. Santi and L. Zardi

1985, 192pp., \$25.00/£22.50 (UK only), ISBN: 0.12.619080.1

Based on the proceedings of the 1st International Conference on Progress in Cancer Research, San Remo, Italy, 1983.

This publication brings together the current work of leading experts investigating the biochemical and cellular processes underlying carcinogenesis and tumour growth.

In the ANALYTICAL CYTOLOGY Series...

Edited by J.S. Ploem

FLOW CYTOMETRY: INSTRUMENTATION AND DATA ANALYSIS

Edited by M.A. Van Dilla, P.N. Dean, O.D. Laerum and M.R. Melamed

1985, 312pp., \$59.50/£52.50 (UK only), ISBN: 0.12.712150.1

Flow Cytometry: Instrumentation and Data Analysis offers the most comprehensive treatment available of flow cytometry and sorting. This technique, by which cells and chromosomes can be sorted, continues to gain importance in biology and medicine.

The volume takes a conceptual approach and the material is largely nonmathematical. Where mathematics is used, the reader is supplied with clear explanations of the physical basis for the equations.

By uniting the scattered literature on this important and useful technology, Flow Cytometry provides a practical reference for researchers and students in the biomedical sciences.

VETERINARY IMMUNOLOGY

P.M. Outteridge

1985, 288pp., \$45.00/£36.00 (UK only), ISBN: 0.12.531130.3

This book is about the immunology of animals of veterinary interest, in particular those of economic importance, such as the ruminant. It is directed towards laboratory workers and post-graduate students wishing to apply basic immunology to veterinary problems. The book places some emphasis on the practical problems of vaccination and diagnosis of infectious diseases. An appendix of methods is included to encourage workers to try new techniques.

Contents: Cellular Immunology. Immunology of Reproduction. Immunoglobulins. Local Immunity. Immunity to Bacteria. Immunity to Viruses. Immunity to Internal Parasites. Immunity to External Parasites. Immunogenetics. Appendix of Methods. Glossary. Index.

IMMUNE INTERVENTION

Volume 1:

NEW TRENDS IN VACCINES

Edited by I.M. Roitt

1984, 160pp., \$27.50/£19.00 (UK only), ISBN: 0.12.593301.0

Contents: Vaccines: Still Needed. J.H.L. Playfair. Attenuation. J.W. Almond and A.J. Cann. Gene Cloning in Vaccine Research. T.J.R. Harris. Synthetic Vaccines. R. Arnon. Idiotypic Vaccines. F.C. Hay, Y. Thanavala and I.M. Roitt. Index.

OXIDATIVE STRESS

Edited by H. Sies

1985, 476pp., \$79.00/£69.00 (UK only), ISBN: 0.12.642760.7

This book provides an in-depth study of the field of oxygen-related damage in biological systems and surveys present knowledge and problems. Oxidative stress is thought to be implicated in processes as diverse as inflammation, ageing, carcinogenesis, drug toxicity and defence mechanisms of the body against protozoa. The topics covered include both molecular events in model systems such as DNA and clinical problems such as inflammation and tumour promotion *in vivo*.

MONOCLONAL ANTIBODIES IN CLINICAL MEDICINE

Edited by A. McMichael and J. Fabre

1982, xiv + 664pp., \$63.00/£42.00 (UK only), ISBN: 0.12.485580.6

The book reviews the major current and projected clinical applications of monoclonal antibodies, and covers a wide field including oncology, haematology, microbiology, neurology, autoimmunity, transplantation, obstetrics, pharmacology and drug targeting. There is an introductory chapter by Dr Cesar Milstein on historical aspects and general principles, and the last section consists of chapters giving detailed methodology on the production of monoclonal antibodies and their use in immunohistology and affinity chromatography, and with the fluorescence activated cell sorter.

RECENT ADVANCES IN SYSTEMATIC LUPUS ERYTHEMATOSUS

Edited by P.H. Lambert, L. Perrin and S. Izui

1984, 280pp., \$35.00/£24.00 (UK only), ISBN: 0.12.434620.0

This book covers both immunological and pathological aspects of systemic lupus erythematosus, deals with recent advances in the basic immunology, genetic regulation, the pathological and clinical expression of the disease and gives emphasis to therapeutic developments.

Contents (Section Headings): Basic Aspects of Autoimmunity. Systemic Lupus Erythematosus at the Gene Level. Lymphocyte Functions and Effector Mechanisms. Pathology of Systemic Lupus Erythematosus. Present and Future Treatment of Systemic Lupus Erythematosus.

JOURNALS IN IMMUNOLOGY

CLINICAL IMMUNOLOGY AND IMMUNOPATHOLOGY

Editors: **H. Hugh Fudenberg**, *Medical University of South Carolina, Charleston*
Robert T. McCluskey, *Department of Pathology, Harvard Medical School*
Massachusetts General Hospital, Boston

Clinical Immunology and Immunopathology is an international medium for the publication of original research concerned with normal and abnormal aspects of clinical immunology and immunopathology. The journal contains articles on timely topics such as immunodeficiency diseases; lymphoplasmocytic dyscrasias; phagocytic functions and defects therein; immunogenetics; cancer immunology; immunohematology; immunoparasitology; autoimmune diseases; complement, kinases (and other mediators); transplantation immunology; immunoneuropathology; immunopharmacology; allergy; immunocyte function, normal and pathologic; immune complex diseases and other immunologically induced diseases; and animal models of human diseases. Reviews of areas in basic immunology are also included on occasion.

Volumes 38-41 (1986), 12 issues (including annual subject index)

In the U.S.A. and Canada: \$380.00 All other countries \$435.00 In the U.K. £322.50
Academic Press U.S.A.

CELLULAR IMMUNOLOGY

Editor: **H. Sherwood Lawrence**, *New York University Medical Center, New York City*

Cellular Immunology is devoted to the publication of original investigations concerned with the immunological activities of cells in experimental or clinical situations. The scope of the journal encompasses the broad area of *in vitro* and *in vivo* studies of cellular responses. Research areas include delayed-type hypersensitivity or cellular immunity, immunologic surveillance and tumor immunity, transplantation immunology, autoimmunity, nonantibody immunity, resistance to intracellular microbial and viral infection, immunologic deficiency states and their reconstitution, and antigen receptor sites.

Volumes 97-103 (1986), 14 issues (including annual subject index)

In the U.S.A. and Canada: \$644.00 All other countries \$745.00 In the U.K. £552.00

Vaccination and herd immunity to infectious diseases

Roy M. Anderson & Robert M. May*

Department of Pure and Applied Biology, Imperial College, London University, London SW7 2BB, UK

* Biology Department, Princeton University, Princeton, New Jersey 08540, USA

An understanding of the relationship between the transmission dynamics of infectious agents and herd immunity provides a template for the design of effective control programmes based on mass immunization. Mathematical models of the spread and persistence of infection provide important insights into the problem of how best to protect the community against disease.

MUCH attention is now focused on the development and community-wide use of vaccines for the control of infectious diseases. This interest is a consequence of many factors; these include the worldwide eradication of smallpox by vaccination in the late 1970s¹, the current success of child immunization programmes for the control of measles, mumps, pertussis and rubella in the United States^{2,3}, the failure of frequent appeals by public health authorities in the United Kingdom to raise vaccination rates that are at present low by developed-country standards⁴⁻⁷, the Expanded Programme on Immunization (EPI) of the World Health Organisation (WHO) for the control of a variety of serious childhood viral and bacterial diseases in the developing world⁸⁻¹², and the rapid advances in molecular biology and biotechnology which promise new vaccines for the future¹³⁻¹⁶. The main thrust of research today is at the molecular level, where it is stimulated by the urgent need to develop vaccines for the major killing diseases of the Third World such as malaria¹⁷⁻¹⁹, and to combat new infections such as the current epidemic of AIDS (acquired immune deficiency syndrome), caused by the recently isolated human T-lymphotropic virus (HTLV-III)^{20,21}.

The development of a safe, effective and cheap vaccine, however, is only a first step (albeit an essential one) towards community-wide control. Epidemiological, economic and motivational issues are at least as important as technological ones. A vaccine for measles (a very cost-effective immunization¹²) has been available since the late 1960s, yet the infection remains one of the world's major causes of child mortality^{8,22}. Concomitant with research on vaccine development, there is a need for an improved understanding of how best to use vaccines to protect the community as well as the individual. The persistence of infectious disease within a population requires the density of susceptible individuals to exceed a critical value such that, on average, each primary case of infection generates at least one secondary case. It is therefore not necessary to vaccinate everyone within a community to eliminate infection; the level of herd immunity must simply be sufficient to reduce the susceptible fraction below the critical point. The central epidemiological questions are thus: what proportion of the population should be vaccinated to achieve elimination (in a local programme), eradication (in a global programme) or a defined level of control? How is this affected by demographic factors (for example, birth rate)? What is the best age at which to immunize? How does mass immunization affect the age distribution of susceptible individuals, particularly in those classes most at risk from serious disease, and how important is genetic and spatial heterogeneity in susceptibility to infection (or response to immunization) to the creation of effective herd immunity²³⁻²⁶?

To answer these questions, we need to understand the interaction between the transmission dynamics of the disease agent and the level of naturally acquired (or artificially created) immunity to infection. This relationship is complex and depends on such factors as the precise course of infection within an individual, the demography of the host population, the duration

of acquired immunity and maternally derived protection, age-related changes in the degree and intimacy of contacts among people, and the prevailing levels of genetic, spatial and behavioural heterogeneity in susceptibility/resistance to infection. Intuition built on many years of practical epidemiological experience often fails to predict the outcome of a particular vaccination programme. Mathematical models which clearly and accurately define the details of the association between disease agent and host (at the individual and population levels) can help to overcome such difficulties. This article reviews recent theoretical and empirical work on the transmission dynamics of infectious disease. Emphasis is placed on the relevance of such research to the design of disease control programmes based on vaccination.

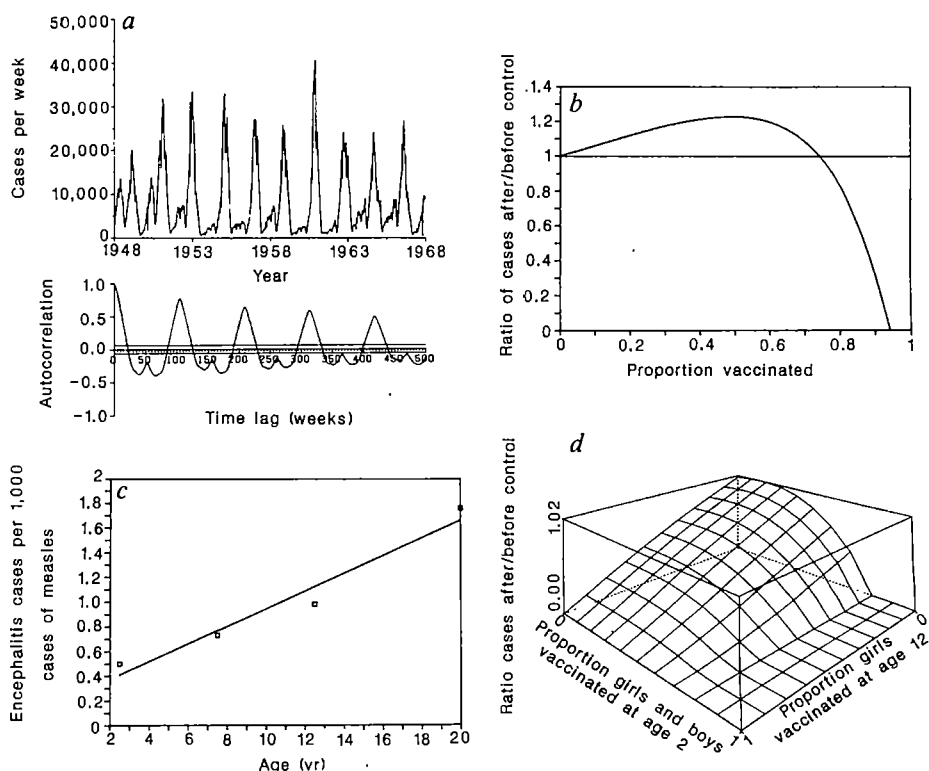

General theory

Models for the transmission dynamics of directly transmitted viral and bacterial infections are typically compartmental in structure²³⁻³⁵. They represent changes, with respect to age, a , and time, t , in the populations of infants protected by maternally derived antibodies ($M(a, t)$), susceptible individuals ($X(a, t)$), infected individuals who are not yet infectious ($H(a, t)$), infectious people ($Y(a, t)$), and people who have recovered and are immune from subsequent infection ($Z(a, t)$). The total population is $N(a, t) = M(a, t) + X(a, t) + H(a, t) + Y(a, t) + Z(a, t)$. The deterministic equations describing the flows from one class to another are of the general form^{24,25,27}

$$\begin{aligned} \frac{\partial M(a, t)}{\partial t} + \frac{\partial M(a, t)}{\partial a} &= -[\mu(a) + d]M(a, t) \\ \frac{\partial X(a, t)}{\partial t} + \frac{\partial X(a, t)}{\partial a} &= dM(a, t) \\ &\quad - [v(a, t) + \lambda(a, t) + \mu(a)]X(a, t) \\ \frac{\partial H(a, t)}{\partial t} + \frac{\partial H(a, t)}{\partial a} &= \lambda(a, t)X(a, t) \\ &\quad - [\mu(a) + \sigma]H(a, t) \\ \frac{\partial Y(a, t)}{\partial t} + \frac{\partial Y(a, t)}{\partial a} &= \sigma H(a, t) - [\mu(a) + \gamma]Y(a, t) \\ \frac{\partial Z(a, t)}{\partial t} + \frac{\partial Z(a, t)}{\partial a} &= \gamma Y(a, t) + v(a, t)X(a, t) \\ &\quad - \mu(a)Z(a, t) \\ \frac{\partial N(a, t)}{\partial t} + \frac{\partial N(a, t)}{\partial a} &= -\mu(a)N(a, t) \end{aligned} \quad (1)$$

Here $\mu(a)$ denotes age-related human mortality, $1/d$ is the average duration of protection provided by maternal antibodies, $1/\sigma$ and $1/\gamma$ are the average incubation and infectious periods respectively, and $v(a, t)$ records the age- and time-specific vaccination schedule. Mortality explicitly associated with the

Fig. 1 *a*, Time series analysis of the case reports for measles in England and Wales over the pre-vaccination period 1948–68. The top graph denotes the recorded cases and the bottom graph the serial correlogram⁵¹. Note the significant yearly (seasonal) and 2-yearly peaks in incidence (the horizontal axis in the bottom graph denotes weeks). *b*, Model predictions of the equilibrium (the state to which the system settles in the long term) ratio of the number of cases of mumps in the age range 14–50 yr (the age range in which males are at risk to serious disease resulting from infection) under the impact of a vaccination programme in which *p* of each yearly cohort are vaccinated at age 2 yr, divided by the number of cases in the same age range before vaccination. If the ratio is above unity, the control programme has a detrimental effect and vice versa. The average age at infection before control was assumed to be 6.5 yr (appropriate for the United Kingdom) and the calculations were based on a model defined in ref. 24. The straight line denotes the ratio of unity. *c*, Age-specific incidence of reported measles encephalitis cases (defined per 1,000 cases of measles) in the United States in 1973–79¹⁶. *d*, Similar to *b* but representing the ratio of cases after vaccination divided by cases before vaccination for rubella in the United Kingdom in the age range 16–40 yr. The graph denotes model predictions (equilibrium values) for a two-stage vaccination policy involving vaccination of only girls at age 12 yr (the UK policy) and vaccination of boys and girls at age 2 yr (the US policy)^{25,67}. Note that the addition of a second-stage US policy over the current UK policy is only of substantial benefit if moderate to high levels of vaccination coverage are achieved at 2 yr of age. The average age at infection before control was assumed to be 9–10 yr of age^{25,67}.

infection has been ignored. The term $\lambda(a, t)$ denotes the 'force' or rate of infection, which under the 'mass action' assumption adopts the form^{24–30} $\lambda(a, t) = \int_0^\infty \beta(a, a') Y(a', t) da'$. Here $\beta(a, a')$ represents the transmission coefficient for infected individuals in age class a' who come into contact with susceptible individuals in age class a (refs 25, 30). The boundary conditions of equations (1) depend on the demography of the community. The structure of the model may be modified to mimic the transmission of a wide variety of infections^{31–34}, including those with complex life cycles (for example, malaria or yellow fever^{35–37}) and those involving carriers (such as tuberculosis and hepatitis B³⁸) or macroparasites (such as helminths) where note must be taken of the distribution of parasite numbers within the human community^{39,40}.

Insights into applied problems of disease control or into general ecological and epidemiological questions can be obtained through analytical or numerical studies of equations (1).

Cycles in incidence

For most common viral and bacterial infections of childhood, the model predicts large-amplitude, slowly damping oscillations in disease incidence^{23–30}. Several factors can tend to perpetuate these oscillations indefinitely; these are stochastic effects^{41–44}, age-dependent transmission rates²⁵, incubation periods of a discrete nature^{45,46} and seasonality in contact^{27,47–50}. The average period of oscillations, T , is approximately given as²³: $T \approx 2\pi(AK)^{1/2}$, where A is the average age at infection and K is the generation time of the infection ($K = 1/\sigma + 1/\gamma$).

The observed periods of such cycles (which agree well with prediction) can be determined accurately by time-series techniques (Table 1a, Fig. 1a⁵¹); the longer-term cycles are usually compounded with short-term seasonal effects.

Vaccination and herd immunity

The basic reproductive rate or transmission potential of an infection, R_0 , is the average number of secondary cases produced by one primary case in a wholly susceptible population^{33,34}. Clearly, an infection cannot be maintained unless R_0 exceeds

unity. Within communities in which the infection is endemic, R_0 is inversely correlated with A , the average age at infection^{23–37} ($R_0 \approx B/(A - D)$). This relation holds both for developed countries (growth rates essentially zero) and for developing countries (with their growing populations)⁵². Here B is the reciprocal of the finite birth rate (usually expressed as births (yr^{-1}) per 1,000 of population), and D is the duration of maternally derived immunity. The value of R_0 within a community is critically dependent on social and behavioural factors (the contact component of β which influences λ and hence A), on the biology of the disease agent and host (the infectiousness and susceptibility components of β) and on the demography of the community (value of B)²⁵. The marked difference between developed and developing countries in the average ages at which children typically acquire infections such as measles in urban communities is a consequence of variations in social, behavioural and demographic factors (Table 1b).

To eradicate an infection by mass immunization it is necessary to reduce the value of R_0 below unity^{23–25,53}. This can be achieved by vaccinating a proportion, p , of each cohort of the population at age V (where $V > D$; vaccination during the period of maternally derived protection usually fails to protect the child adequately from subsequent infection^{54,55}) provided^{23,25} $p > [1 - A/B]/[1 - V/B]$. The infection can never be eradicated if $V > A$ (that is, $p > 1$). The value of p is minimized by vaccinating at as young an age as possible, given the constraint of $V > D$. These conclusions are derived under the assumption that the rate of transmission within the community is fairly homogeneous. In practice, this assumption is often violated^{25,30}, but simple theory provides a useful guide, usually setting an upper limit to the levels of vaccination required to eliminate many common childhood infections²⁵. It forms the basis of estimates suggesting that 92–96% of children must be vaccinated to eliminate measles and pertussis, 84–88% to eliminate rubella and 88–92% to eliminate mumps in Western Europe and the United States; these estimates assume that vaccination takes place just after the wane of maternal antibody protection^{23–25}. Recent experience in the United States suggests that high levels of cohort immunization are required (as indicated by theory)

Table 1 Infections reported throughout the world

a, The inter-epidemic period, T , for various viral and bacterial infections^{23–25,51,99,115}. b, Average age at infection (yr), A , for different diseases in different localities^{23,24,34,99,116}. c, The impact of age-related changes in the force of infection, λ (yr⁻¹), on the critical proportion of the population p , to be vaccinated to eradicate measles in England and Wales^{23–26} (case 1, constant; case 2, age dependent).

to substantially reduce the incidences of common childhood infections.

The vaccination of cohorts must be continued for many decades before the full impact of a programme is manifest; long-term suppression or interruption of transmission requires continual cohort vaccination as long as the infection remains endemic in other communities or countries. The only infection to be eradicated worldwide is smallpox. This success (announced by WHO in 1977) generated some optimism concerning the feasibility of eradicating other major infections, such as measles and pertussis^{8,9,56–58}. Such optimism, however, may be misplaced, given the low communicability of smallpox (low R_0 and high average age at infection, A , before widespread immunization) in comparison with infections such as measles, the ease with which smallpox infection can be diagnosed, the practical simplicity of inoculation procedures and the stability of the smallpox vaccine under primitive storage conditions^{1,59,60}.

Successful immunization programmes may themselves create health problems, since vaccination almost invariably carries some risk (usually extremely small) to the individual. At the start of a mass-immunization programme, the probability of serious disease arising from vaccination is usually orders of magnitude smaller than the risk of serious disease arising from natural infection. As the point of eradication is approached, the relative magnitude of these two probabilities must inevitably be reversed. The optimum strategy for the individual (not to be vaccinated) therefore becomes at odds with the needs of society (to maintain herd immunity). This issue—which was central to the decline in uptake of whooping cough vaccine in the United Kingdom during the mid- to late-1970s—can be overcome by legislation to enforce vaccination (as in the United States), but its final resolution is only achieved by global eradication of the disease agent (so that routine vaccination can cease)⁶¹.

Mass immunization at levels below that required for elimination acts to reduce the number of cases of infection (and hence the force of infection, λ). However, both theory^{23–26} and observation^{62,63} suggest that it has little, if any, impact on the total number of susceptible individuals. If the infection is endemic, its effective reproductive rate is unity—each case produces, on average, one other case—and the fraction susceptible remains roughly constant ($\sim 1/R_0$), independently of whether suscepti-

bility is lost by vaccination or by natural infection. Reduction of transmission via vaccination, however, usually increases the inter-epidemic cycle period and the average age at infection^{23–26,51}. This latter manifestation can be worrying if the risk of serious disease resulting from infection increases with age (Fig. 1c). Whether this issue is important depends on the quantitative details of such factors as how risk changes with age, the average age at which the vaccine is administered, and how the force of infection changes with age before widespread immunization^{25,26} (Fig. 3a). Rubella and mumps are of particular concern because of the risk of congenital rubella syndrome (CRS) in infants born to mothers who contracted rubella in their first trimester of pregnancy^{64,65} and the occurrence of orchitis and the associated risk of sterility in post-pubertal males following mumps infection⁶⁶ (Fig. 1b, c). The problems surrounding mass vaccination against rubella (to control CRS) have resulted in the adoption of different vaccination programmes in different countries. In the United Kingdom, girls only are vaccinated at an average age of around 12 yr, so as to allow rubella virus to circulate and create naturally acquired immunity in the early years. By contrast, in the United States both boys and girls are vaccinated at around 2 yr of age, with the aim of eliminating rubella. Theory suggests that the US policy is best if very high levels of vaccination (80–85% of each yearly cohort) can be achieved at a young age, while the UK policy is better if this cannot be guaranteed^{24,67}. A mixed US and UK policy is predicted to be of additional benefit over the UK single-stage policy if moderate to high levels of vaccine uptake among boys and girls can be achieved at a young age ($>60\%$)⁶⁷ (Fig. 1d).

Epidemiological data

The average age at infection, A , is central to most estimates of the intrinsic transmission potential of an infection, to the calculation of the desired level of vaccination coverage for elimination, and to theoretical assessment of how the risk of serious disease caused by infection may change with age under the impact of mass vaccination. For infections which are thought to induce life-long immunity against disease (for example, measles, mumps, rubella and pertussis), the value of A can be estimated (see Table 1b) either from age-stratified case notification records or, more accurately, from serological profiles (Fig. 2).

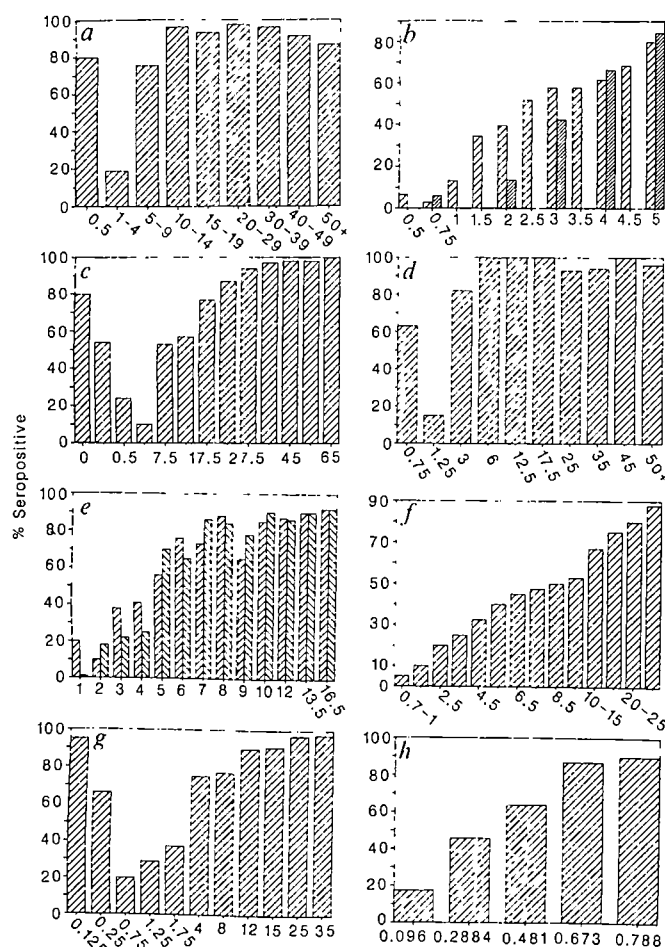

Fig. 2 Age-stratified (horizontal) serological profiles of the percentages of people in different age groups with antibodies to various infectious disease agents in developed and developing countries. *a*, Measles in the United States in 1955-58 (New Haven, Connecticut)¹¹⁷. *b*, Measles in India¹¹⁸ (left-hand histograms) and Nigeria¹¹⁹ (right-hand histograms). Note the rapidity with which the proportion seropositive rises with age when compared with *a*. *c*, Rubella in England and Wales²⁴ in the 1960s and 1970s. *d*, Rubella in the Gambia in the late 1970s¹²⁰. Again note the rapidity of the rise in seropositivity with age when compared with *c*. *e*, Mumps in England and Wales (left-hand histograms) and the Netherlands (right-hand histograms)^{121,122}. *f*, Polio in the United States in 1955-58³⁴. *g*, Hepatitis B (HBV) in Senegal¹²³. The vertical axis denotes the percentage with HBV markers. *h*, Malaria (*Plasmodium falciparum*) in Nigeria¹¹⁵. The vertical axis denotes the cumulative percentage of children who have experienced infection. Note that in *a-h* the scales of the x-axes are not always identical and in certain cases record unequal age class divisions (a nonlinear scale).

The interpretation of the data, however, is beset with many problems, such as age-specific biases in notification records^{68,69}, and a reduced ability to detect antibodies in adults who experienced infection in early childhood⁷⁰.

Heterogeneity in transmission

Conventional epidemiological theory is founded on the 'mass action' principle of transmission (see equations (1)), in which infection is assumed to spread via contacts within a homogeneously mixing community⁷¹. Recent research has begun to take account of the complications induced by heterogeneity in transmission arising from age-related, genetic, spatial or behavioural factors^{25,30,72-77}.

Age-dependent factors. Analyses of case notification records and serological profiles suggest that, for many common infections (measles, rubella and pertussis), the per capita rate of infection ($\lambda(a, t)$) depends on the ages of susceptible individuals, changing from a low level in the 0-5-yr age classes, via a high level in the 5-15-yr age classes, back to a low level in the adult age classes (Fig. 3a)²⁵. This is of interest both because it reflects behavioural attributes of human communities and because of

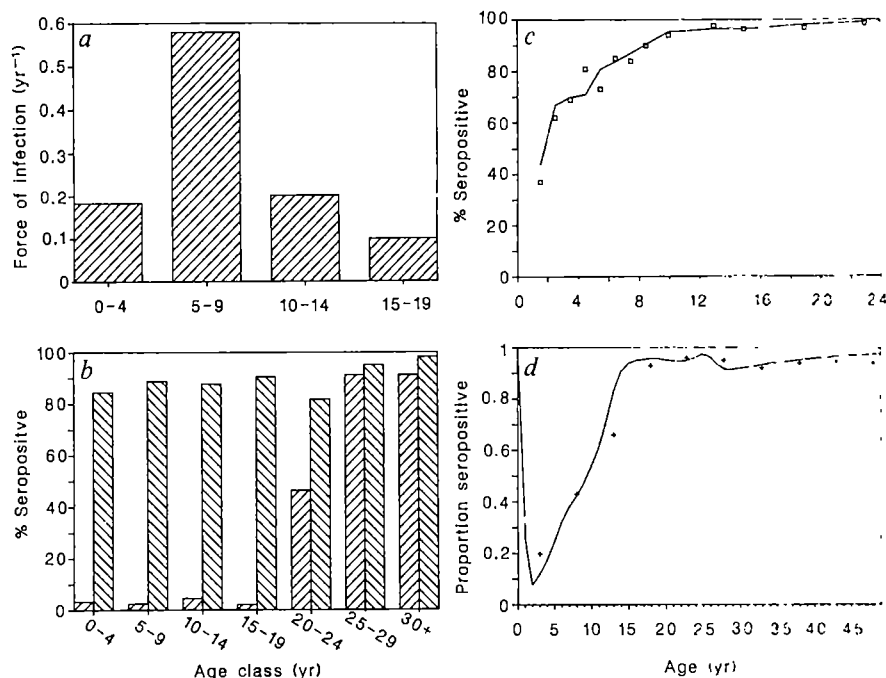

its impact on the level of vaccine-induced herd immunity required to eliminate an infection^{25,67,75}. The high values of λ observed in the 5-15-yr-old classes (Fig. 3a) are thought to arise as a consequence of frequent and intimate contacts within school environments.

Analyses of the significance of age-related changes in contact with infection are crude at present, due to the absence of detailed information on 'who acquires infection from whom'²⁵. Models which incorporate high degrees of contact within school-age classes (and low contact in the very young and in adult age groups), however, yield predictions of temporal changes in disease incidence and of age-related changes in serology in vaccinated versus unvaccinated communities which closely parallel observed trends²⁵ (Figs 3c, d, 4a-c). Recent numerical studies suggest that predictions based on the assumption of homogenous mixing tend to overestimate the critical level of vaccination coverage for elimination by roughly 5% for infections such as measles and pertussis in the United Kingdom and United States (Table 1c)^{25,30}. For these infections, analyses based on apparent age-related changes in contact with infection (Fig. 3a) yield estimates of approximately 90% coverage at 1-2 yr of age²⁵. These predictions, however, must be accepted with caution at present, because the observed low rates of infection in late teenage and adult age groups may be artefacts arising from biases in case reporting, from the insensitivity of serodiagnostic tests, or from genetic variability in susceptibility to infection⁷⁸. These caveats are underlined by the fact that no such marked age-related changes in the per capita rate of infection are found in epidemics within virgin populations on islands (largely susceptible to infection before the epidemic⁷⁹⁻⁸¹) (Fig. 3b). At present it seems prudent to accept the higher vaccine coverage levels estimated by homogeneous mixing models²⁵.

Genetic factors. Genetic factors are important in determining host susceptibility and resistance to infectious agents⁷⁸. Genetically based variability in the level and duration of antibody production following infection would seriously complicate the interpretation of age-serological profiles⁸². Associations between HLA type and antibody titres following vaccination against rubella and measles provide evidence for the existence of such complications^{83,84}. Little is understood, at present, about the importance of such factors in the design of vaccination programmes. In the future, however, community-based diagnostic programmes aimed at the identification of immunodeficiency could make it possible to target vaccination, for certain less-common but serious viral and bacterial diseases, to those children genetically predisposed to infection and severe morbidity⁸⁵.

Spatial factors. Inhomogeneity in the spatial distribution of hosts, with some people living in dense aggregate and others living in isolated or small groups, can lead to heterogeneity in transmission rates. This, in turn, can result in the transmission potential of an infection (R_0) being greater on average than suggested by estimation procedures which assume spatial homogeneity^{86,87}. Under these circumstances, the optimal solution appears to involve 'targeting' vaccination coverage in relation to group size, with dense groups receiving the highest rates of vaccination⁷⁴. The optimal programme is defined as that minimizing the total, community-wide number of immunizations needed for elimination or a defined level of control. This strategy reduces the overall proportion that must be vaccinated to achieve elimination, compared with that estimated on the assumption of spatial homogeneity. This conclusion has practical significance for the control of infections such as measles and pertussis in some developing countries, where rural-urban differences in population density tend to be much more marked than in developed countries. It is probable that in many regions of Africa and Asia, diseases such as measles cannot persist endemically in rural areas without frequent movement of people between rural and urban regions ($R_0 < 1$ in rural areas). Under these circumstances, disease control might be achieved in both types of region by high levels of mass immunization in the urban centres alone.

Fig. 3 *a*, Age-specific change in the rate, or force, of measles infection (λ) in England and Wales before mass vaccination²⁵. *b*, Percentages seropositive for rubella antibodies in various age classes on St Paul's Island, Alaska, before (left-hand histograms) and after (right-hand histograms) an epidemic of rubella in 1963⁷⁹⁻⁸¹. The population (~400 people) had not experienced rubella infection (before 1963) for 22 yr. Note that in the age range 0-19 yr, the rate of infection of susceptible individuals was similar in each age class. *c*, Comparison of model predictions (equations (1)) of the age-serological profile for measles antibodies in England and Wales with observed patterns. The observed data (squares) were collected in the period 1979-82. Model predictions were based on an average age of infection of 4.5 yr before control and the age-specific vaccination rates in the United Kingdom over the period 1968-82²⁵. *d*, Comparison of model predictions of the age-serological profile for rubella antibodies in females in England and Wales with the observed pattern (crosses) in 1984⁶⁷. Predictions were based on an average age of infection of 10 yr before control and the age-specific vaccination rates in the United Kingdom (vaccination of teenage girls between the ages of 10 and 15 yr) over the period 1970-84.

Behavioural factors. These are of great importance as determinants of disease transmission and provide a source of significant heterogeneity. The sexually transmitted infections provide a good example because the probability distribution of sexual promiscuity (defined as the number of different sexual partners per unit of time) is highly skewed. It seems very likely that the highly sexually active individuals ($R_0 \gg 1$) in the tail of the distribution are responsible for maintaining transmission within the community as a whole⁸⁸⁻⁹⁰. Drug treatment and surveillance focused on these 'superspreaders' is therefore highly beneficial, given that R_0 may be below unity for the remaining population. If vaccines are developed for HTLV-III, selective immunization of those most at risk⁹¹⁻⁹³ (haemophiliacs, intravenous drug abusers, persons of Central African or Haitian origin and homosexual males) and those predisposed to serious clinical infection, may be a practical option for community-wide control.

Behavioural factors are also important in helping to cause seasonal fluctuations in the incidence of many common viral and bacterial infections^{49,75,94}. The timings of school terms and vacation periods has a marked influence on temporal patterns of measles and pertussis cases in the United Kingdom and West Germany, for example.

Developing countries

Many infections that in developed countries are primarily a source of morbidity are major cause of mortality in the developing world (mainly as a consequence of malnutrition, although genetic components may also be involved)^{9,22,95}. Measles, for example, is estimated to cause more than one million child deaths annually^{9,22}. Although there is much current interest in worldwide immunization programmes for the control of such infections, the problems of creating sufficient levels of herd immunity for elimination should not be underestimated, given the logistic difficulty of vaccine storage and delivery in poor countries. Even if such practical issues are resolved by effective cold-chains, the development of heat-stable vaccines, and aerosol delivery techniques (which are more effective in the immunization of infants with maternal antibodies)⁹⁶⁻⁹⁸, the feasibility of blocking transmission by mass vaccination in areas where the average age of infection is often as low as 1-2 yr of age is questionable (Table 1b).

Consider a large urban centre in India or Africa, where the annual birth rate is around 40 per 1,000 population and the average age of measles infection is 2 yr (Fig. 2). Vaccination must take place after the maternally derived protection has

waned (6 months) and before the age of 2 yr to achieve elimination. Calculations suggest an R_0 value of around 17, which is similar to that for measles in England and Wales (with a birth rate of 12 per 1,000 and an average age of infection around 4.5-5 yr). Simple theory suggests that something like 96% of each yearly cohort of children would have to be effectively immunized by age 1 yr ($V=1$) to attain elimination. Coverage could be lower in rural areas but, as suggested in the section on spatial heterogeneity, an optimal control programme would have to focus on the urban centres. These estimates question the feasibility of measles elimination in many developing countries at this time and argue that, as a first priority, worldwide programmes should concentrate on controlling morbidity and mortality among those most at risk^{52,99}. Moderate to low levels of vaccination coverage, however, are beneficial; they raise the average age at infection and thereby lengthen the age 'window' in which vaccine can be administered⁹⁹, and reduce morbidity and mortality (young infants appear to be more at risk than older children).

New vaccines

The coming decade will see the development and use of a number of new vaccines, along with the expansion of community-based programmes of mass immunization using the currently available vaccines. The development of safe, effective and cheap vaccines is clearly the first priority, but, once these objectives are achieved, the problem of community-wide control requires careful attention. In particular, age-specific serological profiles of the community need to be obtained both before and during any programme of mass vaccination.

An example is provided by the recent proposal to initiate a mass-vaccination campaign for the control of hepatitis B virus (HBV) in Taiwan¹⁴ by a serum-derived vaccine (a genetically engineered vaccine is also available^{100,101}; Fig. 2). The epidemiology of HBV is made complicated by chronic infection in immunodeficient individuals who become carriers of the virus (with a high associated risk of inflammatory disease and malignancy)¹⁰², and who constitute an important reservoir of infection. The desirability of mass immunization is clear when viewed as a method for reducing the incidence of carriers (the risk of becoming a carrier appears to be much greater in children than in adults¹⁰³), but less clear given the observation that serious symptoms of disease are more likely to occur in adults than in children. Serological surveys in high-risk regions (South-East Asia and Africa) indicate that HBV typically has a low R_0 within the population as a whole (when compared with measles).

Moderate levels of vaccination coverage should therefore have a significant impact on disease incidence^{23,102,104} (Fig. 1d). The calculation of R_0 is made complicated by the presence of carriers ($R_0 = R_{01}f + R_{02}(1-f)$, where f is the fraction of carriers and $(1-f)$ the fraction of non-carriers) and a component of perinatal (=vertical) transmission⁴². The maintenance of transmission ($R_0 > 1$) is probably due to the carriers alone ($R_{01} \gg 1$, $R_{02} < 1$) given that they are often a significant fraction of the community (with f values ranging from 0.1% to 2% in the United States and most European countries, to as high as 50% in certain Pacific islands (determined in part by the ethnic composition of a community¹⁰²)).

Vaccines for viral infections such as cytomegalovirus, rhinovirus, adenovirus, rotavirus, respiratory syncytial virus and parainfluenza virus may provide sufficient protection to the individual to be considered for community-wide use in the future, provided their public health significance is of sufficient importance relative to other priorities in health care. The existence of many distinct antigenic types within certain groups of these viruses (for example, adenovirus and rhinovirus), however, present problems for vaccine development.

Recent work has raised the hope that vaccines may be developed for the major parasitic infections such as malaria (*Plasmodium falciparum*) and certain helminth species¹⁰⁵. The problems, however, are formidable because of the antigenic complexity of protozoa and helminths (in comparison with viruses and bacteria)¹⁰⁶, sequential changes in surface antigens during development within the host (for example, the filarial worms)¹⁰⁷, antigenic variation (whether due to the parasite's ability to express many variable antigen types, as in the case of the African trypanosomes^{108,109}, or as a consequence of population genetic (=strain) variability, as in the case of the malaria parasites¹¹⁰), and the failure of man naturally to develop fully protective immunity under conditions of repeated exposure to infection¹¹¹. Vaccines must be more effective in stimulating the host's immunological defences than the parasite itself if they are to overcome the evasion mechanisms that certain parasitic species have evolved¹¹². Combined with these problems is the suspicion that heterogeneity in immunological responsiveness is an important determinant of the observed aggregation in the distribution of parasite numbers per person (such that 15% of the hosts will often harbour 90% or more of the parasites)^{39,40,113,114}. Predisposition to heavy or repeated parasitic infection is often a consequence of behavioural or social factors but laboratory studies increasingly point to the importance of genetic and nutritional components¹¹². An effective vaccine must therefore be able to protect both immunocompetent and immunodeficient individuals, the latter being those most likely to suffer serious disease and to maintain parasite transmission.

The ideal malaria vaccine will probably contain antigens from different malaria species, strains and developmental stages (sporozoite, asexual and gamete) so as to reduce mortality and morbidity, and to block transmission^{18,19}. But once the technical problems in vaccine development have been overcome, the issues of community control must take priority. The creation of a level of herd immunity high enough to eliminate malaria appears impractical in endemic regions where the average age at first infection is typically around 3–6 months of age ($R_0 = 50$ –100, which implies 99% coverage of the community before the age of 3 months with a vaccine which gives lifelong protection) (Fig. 1e). Low to moderate levels of immunization, however, will greatly help to control mortality and morbidity, which is of greatest significance in the 0–5-yr-old age classes. Care must, however, be exercised to prevent an associated build-up of susceptible individuals in teenage and adult age classes; at present, such individuals have acquired a degree of immunity to infection from repeated exposure in childhood. Once the properties of a potential vaccine are more clearly defined, mathematical studies can help to quantify such risks. In the case of helminth infections, vaccines will probably only provide protection of short duration against re-infection, and

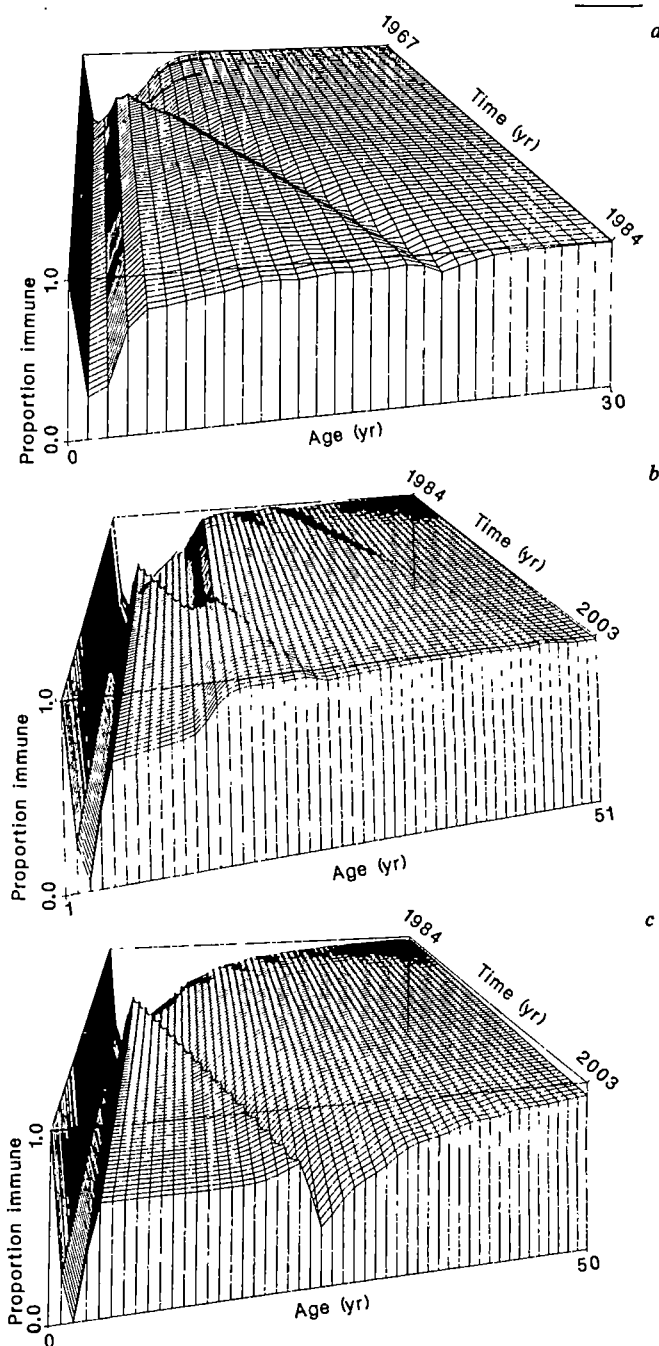

Fig. 4 a, Model predictions (equations (1)) of the impact of mass vaccination on the age-serological profiles for measles antibodies (the proportion in each age class who are immune either as a result of maternally derived protection (in the infants), recovery from natural infection, or vaccination) in England and Wales²⁵. Mass vaccination was introduced in year 1 (year 0 denotes the pre-vaccination profile, based on the age-specific forces of infection defined in Fig. 3a) and maintained for 16 yr with the age-specific vaccination rates recorded in England and Wales (mean age at vaccination ~2.2 yr; ~50–60% of each yearly cohort was immunized by age 5 yr). The age axis denotes the intervals 0, 0.5, 1.0, 2.5, ... etc. yr. Note how mass vaccination (in the age range 1–3 yr) acts to decrease the proportion seropositive in the older age classes (by reducing the overall force of infection within the community below the level in the pre-vaccination community). The valley of seronegativity running diagonally across the surface denotes the ageing of the last cohorts of young children to be excluded from mass immunization (see ref. 25 for further details). b, c, Similar to a but denoting model predictions of the impact of vaccination on the age-serological profiles for rubella antibodies over the period 1984–2030 in the United Kingdom in the male (c) and female (b) segments of the population. The basis of the predictions is described in ref. 67. In the period 1970–84 a single-stage UK policy was in operation (vaccination of teenage girls between the ages of 10–15 yr, with the observed vaccination rates for England and Wales). In 1985 a two-stage (UK-US) policy was begun (vaccination of teenage girls at 1984 rates, vaccination of 60% of 2-yr-old boys and girls) to be maintained up to 2030. Note how the introduction of the two-stage policy alters the level of herd immunity in both the male and female segments of the population. The age axis records the intervals 0, 0.5, 1.5, 2.5, ... 49.5 yr.

hence the creation of herd immunity may require repeated cohort immunization. Cost factors and other practical issues are therefore likely to be of great importance in developing countries when considering the benefits of mass vaccination versus mass chemotherapy.

Conclusions

Many difficulties surround the attainment of sufficient levels of herd immunity to eradicate common infections in developed and developing countries. Theory can define the level of vaccination coverage required for elimination, but success in practice depends on economic and motivational issues. Vaccines against protozoan and helminth parasites will undoubtedly be of importance in the future (certainly to the Western traveller to tropical regions, but less certainly to those who live in these areas), and research towards their development must remain a priority. This emphasis, however, should not distract attention from the importance of epidemiological research. Effective community-

wide control of many of the world's major infections is likely to depend on integrated approaches, involving some combination of selective or targeted vaccination and chemotherapy (directed towards those most predisposed to infection and morbidity), vector control and efforts to improve nutrition, hygiene, sanitation and education. Insights founded on an understanding of the population dynamics of infection will, therefore, be of great importance in any quantitative assessment of control policy. The recent convergence of mathematical theory and observation in epidemiology has created a powerful set of tools for the design and evaluation of community-based programmes of disease control, provided they are used sensibly. At present the potential value of these techniques is not widely appreciated.

Continental rifts as a setting for regional metamorphism

Stephen M. Wickham* & E. Ronald Oxburgh

Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK

During very high-temperature/low-pressure Hercynian metamorphism in the Pyrenees the crust began to melt at ~12 km and stable isotopes show that it was flushed by circulating seawater to that depth. There is no evidence for crustal collision and the tectonic setting for this, and maybe all high-temperature/low-pressure metamorphism, is a zone of continental rifting.

RIFT valleys are familiar features of the Earth's surface. Some, such as the Rhine Graben, are active today and have associated earthquakes and volcanic activity; others, such as the Midland Valley of Scotland, may be recognized only by the presence of a down-faulted belt of younger rocks preserved in a more ancient terrane. Such rifts must have some expression deeper in the crust, but, at present, its nature is unknown, and there is no way of recognizing them in ancient and deeply eroded areas. Here we link continental rifting in a genetic association with high-temperature/low-pressure (high-*T*/low-*P*) regional metamorphism, an equally common crustal feature but one of uncertain tectonic setting. We argue that the transient physical conditions required for the metamorphism can probably be attained only during rifting; and that the geophysical signatures characteristic of the crust below an active rift can best be satisfied by rocks with the physical properties of those undergoing very high grade metamorphism. We support these conclusions with a detailed study of an exceptionally well exposed Hercynian metamorphic terrain in the eastern Pyrenees.

Eastern Pyrenees

In the Pyrenees, regional early Tertiary uplift has exposed an extensive Hercynian basement terrain (Fig. 1) including abundant granitoid intrusives and several condensed metamorphic sequences that imply exceptionally high thermal gradients^{1,2}. Subsequent Alpine metamorphism and deformation has been slight and is confined to the main fault zones. In between these faults, relatively pristine slices of basement have been differentially elevated and, in consequence, well-preserved Hercynian rocks from a variety of structural levels are often clearly exposed in high mountainous terrains. These range from Upper Carboniferous/Lower Permian sedimentary strata and volcanics,

through Lower Palaeozoic metasediments to granulites from deep crustal levels.

The Trois Seigneurs Massif (Fig. 1) is a thrust slice of Hercynian basement occurring to the north of the zone of maximum uplift. Here, a complete section from fossiliferous Silurian shales through andalusite and sillimanite schists to migmatites and a heterogeneous S-type granitoid is clearly exposed. A section through part of the metamorphic sequence is shown in Fig. 2. The lithologies in the sequence are dominantly pelitic but rare, thin carbonate bands are also present and provide a complimentary control on metamorphic grade. A variety of lines of petrological evidence³ indicate that the onset of melting in the field sequence (believed to correspond to the first appearance of migmatites) was at ~700 °C and at 3.0–3.5 kbar: this conclusion is supported by field and petrographic evidence (see below) and by experimental melting studies on the pelities carried out over a wide *P/T* range, with various water activities. Metamorphism and anatexis occurred under water-rich conditions with *a*_{H₂O} buffered externally near unity, leading to the generation of large quantities of granitic melt from the pelitic rocks³.

Metamorphism and melting were accompanied by deformation and the formation of flat-lying isoclinal folds with axial surfaces parallel to the isograds in all the higher grade rocks^{1,4,5}, but this deformation had mostly ceased before the metamorphic peak was reached because some of the prograde minerals overgrow these structures. Synmetamorphic leucogranite pods generated by partial melting of pelitic metasediment are commonly boudinaged and extended parallel to the isograds. Both of these extensional deformations have previously been attributed to doming by granitic diapirs⁴ but the boudinage (and possibly other deformational features) could equally well result from regional ductile extension of the metamorphic and granitic rocks. Similar metamorphic sequences are exposed elsewhere in the Pyrenees (for example, in the St Barthelemy Massif^{6,7}).

* Present address: Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California 91125, USA.

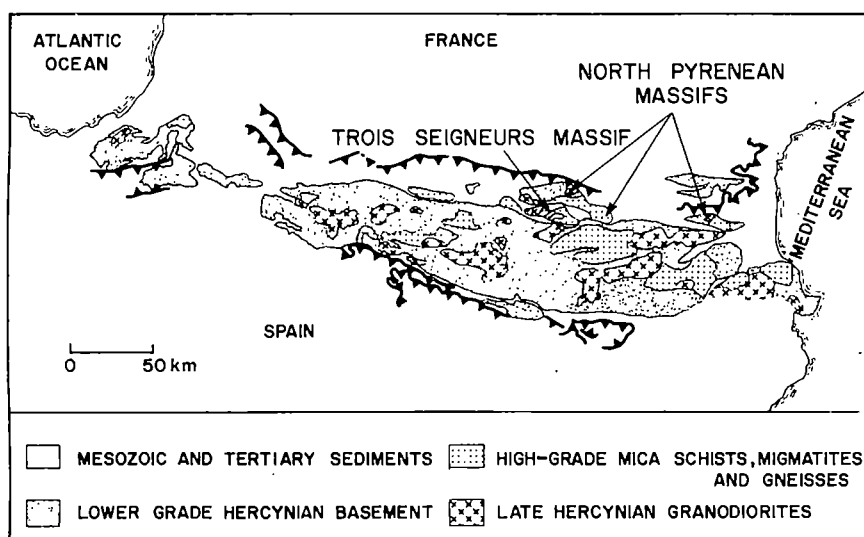

Fig. 1 Map showing the extent of Hercynian basement outcrop in the Pyrenees. The locations of the Trois Seigneurs Massif and other North Pyrenean Massifs are shown.

Fig. 2 Simplified cross-section through the Trois Seigneurs Massif showing the gradational transition from chlorite grade phyllites, through andalusite- and sillimanite-bearing mica schists to migmatites and a per-aluminous granitoid derived by partial melting and homogenization of the pelitic rocks. Note the proximity of low- and high-grade rocks.

Detailed mapping has established that little penetrative deformation has affected the metamorphic sequence since the Hercynian, and it is possible to estimate a thermal gradient for the upper part of the Hercynian crust by measuring the 'stratigraphic distance' (Fig. 2) across a series of isograd surfaces to which temperatures have been assigned. Absolute pressure for the onset of melting can independently be fixed at 3–3.5 kbar by a variety of constraints³, including the mineralogy of the metamorphic sequence (andalusite-sillimanite facies series, staurolite absent, garnet absent except at very Mn-rich compositions), the sequence of isograds (sillimanite in—muscovite out—melting begins), the fact that biotite is a stable phase throughout melting, and the use of biotite-cordierite geobarometry⁸. Having fixed these pressure limits, water activity is also constrained to be high because of the isograd sequence and because biotite persists throughout melting (see refs 3, 9). Where the bases of the high-grade metamorphic sequences are exposed they are seen to pass downwards through migmatite zones into anatectic granites containing disorientated fragments of the more refractory constituents of the former country rock.

The metamorphic reactions corresponding to the isograds documented in the field give a P/T array with a slope of $80\text{--}100\text{ }^{\circ}\text{C km}^{-1}$ for the Hercynian upper crust during metamorphism in the Trois Seigneurs Massif (Fig. 3). Similar metamorphic sequences in many other parts of the Pyrenees^{1,10,11} imply that exceptionally high gradients were developed on a regional scale. Note that slopes of such P/T arrays do not necessarily correspond to true crustal thermal gradients, insofar as the conditions corresponding to the P/T points in the array may have been attained at different times [see ref. 12]. Without a proper understanding of the processes controlling heat and cooling, the significance of such an array is ambiguous.

Hercynian crust during metamorphism

If the P/T array shown in Fig. 3 corresponds to a temperature gradient that existed within the upper part of the Hercynian crust, it could not have continued to depths ≥ 14 km without almost total melting of the crust below this depth, regardless of lithological composition or water content. A similar conclusion is reached by considering the average thermal gradient for the upper crust derived by joining any point in the array to a mean value for the surface temperature.

The crustal temperature distribution implied by these observations cannot represent a steady state: both the geological and geobarometric evidence indicate that the exceptionally high temperatures were not attained by burial, thereby leaving several alternatives. Heat could have been advected to the upper crust

by magma or other fluids from, say, the lower crust or the mantle^{13,14}. A mafic magma could, if present in sufficient quantity and emplaced at a suitable depth (say, 15 km), maintain for a limited period the conditions observed. Such an intrusion would, however, have to be a significant fraction of the crustal thickness (~ 10 km).

Alternatively, high temperatures in the upper crust could have been brought about by a change in the temperature at the base of the crust and thus an increased crustal conductive heat flow. An increase in the temperature at the base of the crust sufficient to give the observed upper crustal conditions, would inevitably also be high enough to melt the lower crust (for any reasonable composition, wet or dry) and in this case heat would be transferred advectively by the ascent of granitoid plutons [see for example, refs 4, 15].

Other evidence

Four other lines of evidence constrain the behaviour of the crust in the eastern Pyrenees during the metamorphic and deformational processes described above.

(1) Extensive granodioritic bodies (such as Mont Louis, Maladeta, and Querigut) have penetrated the whole area; they cut all other lithologies described above and develop contact metamorphic aureoles against them. They were, however, probably emplaced shortly after the cooling of the metamorphic

Fig. 3 Observed Trois Seigneurs P/T array compared with typical geotherms for a stable craton and 20-Myr-old oceanic crust. Anatexis of pelitic metasediment in the Trois Seigneurs migmatite zone occurred at $700\text{ }^{\circ}\text{C}$ and 3.0–3.5 kbar.

sequences (see below) and their isotopic and bulk chemical properties suggest that they were derived from the deeper crust^{16,17}. This shows that partial fusion of the Hercynian crust was not restricted to the anatectic zones described earlier. It is, therefore, possible, although on the grounds of timing not likely, that the ascent of the granodioritic magmas transported heat for upper crustal anatexis.

(2) There is local evidence for the incorporation of mafic material in the main, high level, anatectic zone. At higher structural levels mafics are virtually unknown. If the upper crust was heated by the intrusion of mafic magmas, they must mostly have ponded in the middle crust and risen little above that level.

(3) In various places in the eastern Pyrenees, fault-bounded slices of granulite and amphibolite facies gneisses are exposed (see refs 14, 18). The age of these bodies is not well established but in all probability their main metamorphic mineral assemblages are Hercynian, and in any case not younger. Different slices show equilibration temperatures around 700–850 °C and 3.5–7 kbar (ref. 14). Many of them also show evidence of small scale partial melting with development of leucosomes. If these rocks are Hercynian in age they show that the 'middle' crust (for a conventional crustal thickness) was close to its melting temperature at that time. The slices were emplaced to their present levels as a result of Tertiary deformation.

(4) Whereas the previous three considerations relate to the middle and deeper part of the crust during metamorphism, stable isotope studies can be used to constrain processes nearer the surface. Oxygen isotope studies were carried out on 95 rocks and minerals at different levels in the metamorphic sequence. It was shown¹⁹ that in the Trois Seigneurs Massif, the isotopic composition of oxygen at all exposed levels deeper than the andalusite-in isograd has been homogenized at $\delta^{18}\text{O}$ values of +11 to +13‰. Original values in pelitic lithologies would have been about +15‰. Material balance calculations suggest that isotopic compositions were homogenized by contact with a circulating volume of aqueous fluid with total mass probably >30% of the mass of rock affected¹⁹. This means that the fluid is almost certainly of external origin. Deuterium/hydrogen studies on the same material indicate that the fluid was rich in D with a δD of –10 to –15‰. This corresponds to a probable value for late Carboniferous seawater. These considerations suggest, therefore, that the metamorphic-anatectic sequence and the overlying sediments were flushed by circulating seawater during or before the metamorphic maximum.

Pyrenees in the late Palaeozoic

We now examine some broader aspects of the geology that relate to the regional setting of the Hercynian metamorphism in the Pyrenees to see to what extent they are compatible with rifting.

Within the Pyrenees the Palaeozoic sequence that subsequently underwent Hercynian metamorphism extends from the Cambrian to various horizons in the Carboniferous and comprised shales (dominantly), impure sandstones, carbonates and locally quartzites. There is relatively good palaeontological control of ages and the Devonian and Carboniferous are effectively unmetamorphosed. Conversely the highest grades of metamorphism are restricted to the Cambro-Ordovician rocks. The youngest strata in the Trois Seigneurs area are Silurian, but nearby in the Axial Zone the Westphalian (298–315 Myr) is present. Note that the cooling ages of the Trois Seigneurs granodiorite (post-metamorphic) and probably also the metamorphic sequence are 315 ± 10 Myr. This implies that metamorphism of the lower parts of the sedimentary pile was taking place at the same time as deposition was continuing at the surface. The metamorphic maximum was shortly followed by the ascent of granodiorite bodies that show discordant relations with both metamorphosed and unmetamorphosed Palaeozoic. However, the isotopic composition of oxygen in the Trois Seigneurs granodiorite is undisturbed and so the high level hydrothermal circulation that affected the metasedimentary sequence had ceased before its emplacement.

This main sequence of Palaeozoic deposits in the Pyrenees is terminated by an unconformity at which conglomerates, volcanics and continental deposits of Permian or even Stephanian age commonly overlie Westphalian rocks. The time interval represented by the unconformity varies from place to place.

Ophiolitic rocks have not been reported from the Hercynian Pyrenees nor is there any other evidence of involvement of oceanic rock types. There has, however, been substantial Mesozoic and Tertiary movement of Iberia with respect to France and the early Mesozoic position of Iberia cannot be established with confidence. There is even less control on its relative position in the late Palaeozoic, and therefore it is not clear which areas outside the Pyrenees themselves comprised their Palaeozoic regional setting. However, there does seem to be a direct connection between the Carboniferous of the western Pyrenees and that of the eastern Cantabrian mountains of northern Spain. Upper Carboniferous sedimentation is there characterized by the development of locally very thick successions in small but deep basins. Strikingly angular unconformities punctuate the Upper Carboniferous from the Lower Westphalian to the Lower Autunian. The main sedimentary characteristics are high sediment input, very thick successions (up to 6,000 m locally with a total thickness >15,000 m), rapid changes of facies, both vertically and laterally, and indications of contemporaneous gravity driven movement. These features led Reading²⁰ to propose that they represented deposition in extensional regions developed within a strike-slip orogenic belt, movement probably being accommodated on NW-SE and WNW-ESE trending dextral faults, a direction that is compatible with the regional movement of Africa with respect to Europe and North America at that time¹².

Carboniferous rocks are not exposed immediately north of the Pyrenees in the Aquitaine basin, but, in any case, Iberia was probably closer to Brittany and south-west England at that time. Arthaud and Matte²¹ have summarized the evidence that during Carboniferous and Permian time much of southern and central Europe was affected by rifting.

The setting of Hercynian metamorphism in the Pyrenees is poorly constrained. There is no evidence of continental collision or ocean closure. There was, however, contemporaneous rifting outside the area, and possibly strike-slip movement²¹. Metamorphism seems to have occurred towards the end of a prolonged period of basin subsidence and deposition. Both the evidence of deep circulation of seawater through the sedimentary pile and geochronological evidence suggest that the region was below sea level and still receiving sediment while metamorphism was going on at depth.

A rifting setting

The sequence and timing of events documented above is quite different from that recorded from areas such as the Alps and Himalayas where metamorphism has followed crustal collision and tectonic burial. Metamorphism in a collision setting is typically associated with: (1) nappe-type folding and/or thrusting on a regional scale; (2) a delay of some tens of millions of years between collision (and thus the termination of sedimentation) and the metamorphic maximum; (3) the early development of high-pressure mineral parageneses; (4) the common, but not ubiquitous, preservation of lithologies derived from former oceans. None of these features is present in the Hercynian of the Pyrenees.

Active rifts have been studied in many parts of the world^{22,23}. Some, such as the East African Rift and the Rhine Graben seem to be purely extensional features²⁴. Others, such as the Salton Sea and the Dead Sea, are extensional features associated with major strike-slip movements. Typically they are seismically active, topographically low and continue to receive sediment throughout their active lives. Some such as the Central and Viking grabens of the North Sea are localized zones of extension within a regional extensional basin. The rifts commonly have associated volcanism, hydrothermal activity, and high, but variable, surface heat flow.

Fig. 4 Schematic tectonic setting for the Hercynian high- T /low- P metamorphism in the Pyrenees. Seawater circulates within the Palaeozoic sedimentary pile, towards the bottom of which metamorphism and large-scale anatexis is occurring at 700 °C and 10–12 km depth. The lower crust is heated to very high temperatures by hot, upwelling asthenosphere, and large bodies of granodiorite magma are generated within this deeper melting zone.

Among the most important geophysical features of presently active rifts are the anomalously low crustal seismic velocities recorded beneath them, and the anomalous attenuation of seismic waves passing through them. Both features may be explained by abnormally high crustal temperatures leading to varying degrees of partial melting. Indeed it is difficult to find any plausible alternative.

Probably the most appropriate modern-day analogue for the processes we propose is to be found in the Salton Sea area of southern California²⁵. The regional tectonic setting is one of strike-slip and extension, associated with the southern continuation of the San Andreas fault system and the extensional regime of the Gulf of California spreading centre. In the latter area, the regional heat flow is $\sim 130 \text{ mW m}^{-2}$ but in the Salton Sea area and some of the associated geothermal fields the heat flow is much higher; temperature gradients of $>150 \text{ }^{\circ}\text{C km}^{-1}$ are measured over the upper 2 km. Locally, there are substantial surface flows of hot water and the drilled sections are, and have been, clearly flushed with hot brines. Muffler and White²⁵ document a series of low-pressure/high-temperature prograde metamorphic reactions from cores in the drilled section.

Although the other rifts, such as the Rhine Graben and the Rio Grande Rift, are associated with high heat flow and local magmatic activity the hydrothermal surface manifestations are less extreme than those observed in the Salton Sea. Seismic reflection work²⁶ indicates the presence of a magma body at 19–20 km depth under Socorro in New Mexico in the southern part of the Rio Grande Rift. There is no way of knowing its temperature or composition but it could be sufficiently hot to

bring about partial melting in the crust immediately above it, providing an analogue for the Trois Seigneurs migmatite. Both P - and S -wave velocities are lower under the Rio Grande Rift than in the regions to either side²⁷.

Discussion and conclusions

The relationship between thermal and mechanical phenomena in rift zones is incompletely understood. It is, however, plausible that the maximum perturbations of crustal temperature should occur where the lithospheric thinning is greatest. Stretching may extend uniformly along a rift or may occur heterogeneously beneath a series of staggered, *en echelon* pull-apart basins. In either case, there may be mafic magmatic activity and the temperature at the base of the crust is elevated as a consequence of lithospheric thinning (Fig. 4); the possible importance of such zones for metamorphic processes has been noted by others^{28–30}. Such zones seem to offer the best possibility for attaining the upper crustal P/T conditions described earlier, and a very hot and partially molten middle and lower crust is suggested both by the attenuation and velocity reduction observed across active rifts today, and by the migmatites and the granulite slices from the Hercynian Pyrenees.

We conclude that the Hercynian 'orogeny' in the Pyrenees was a rifting event, possibly associated with strike-slip motion, that affected a continuously subsiding Palaeozoic Basin; that the deformation and metamorphism occurred well below sea level and that seawater was circulating into the crust to depths of 10 km or more during the process. Such an interpretation is consistent with the regional geology of western Europe at that time.

Rifts probably provide a wide spectrum of crustal environments, but virtually all seem to lead to abnormally high crustal temperatures and thus the possibility of high-temperature/low-pressure metamorphic conditions. Whether seawater flushing occurred in any particular instance, would depend on the degree of local extension (and thus subsidence) and access to the sea. The high-temperature/low-pressure elements in the so-called paired metamorphic belts of the Pacific region probably develop by rifting and extension within island arcs. The tectonic interpretation of high temperature belts in old crustal terrains must be reconsidered if the views presented here are correct.

Some of the work described forms part of a thesis by S.M.W., supported by a NERC research studentship, a research fellowship at Trinity Hall, Cambridge, and both a six-month special graduate studentship and a visiting associateship at the California Institute of Technology. Topology of signal recognition particle receptor in endoplasmic reticulum membrane

Leander Lauffer*, Pablo D. Garcia*, Richard N. Harkins†, Lisa Coussens†, Axel Ullrich† & Peter Walter*

* Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, USA

† Departments of Molecular Biology and Protein Biochemistry, Genentech, Inc., 460 Point San Bruno Boulevard, South San Francisco, California 94080, USA

The signal recognition particle (SRP) receptor is an integral membrane protein of the endoplasmic reticulum which, in conjunction with SRP, ensures the correct targeting of nascent secretory proteins to this membrane system. From the complementary DNA sequence we have deduced the complete primary structure of the SRP receptor and established that its amino-terminal region is anchored in the membrane. The anchor fragment and the cytoplasmic fragment contribute jointly to a functionally important region which is highly charged and may function in nucleic acid binding.

WE have recently reviewed the function of the signal recognition particle (SRP) and the SRP receptor in the translocation of secretory and lysosomal proteins across the endoplasmic reticulum (ER) membrane, as well as their function in the integration of certain classes of integral membrane proteins into this membrane¹. SRP is thought to recognize the signal peptide on the nascent proteins and arrest their translation in the cytoplasmic space. On interaction of the elongation-arrested ribosome with the ER membrane, which involves a direct interaction of the ribosome-bound SRP with the SRP receptor in the ER membrane, the elongation arrest is released. The SRP receptor is required for protein translocation even in the absence of elongation-arrest², and it thus seems to function primarily to target the SRP-associated nascent polypeptides to the ER membrane. Thereafter, a functional ribosome-membrane junction is established that allows the translocation of the growing polypeptide chain across the ER membrane by a mechanism that is, as yet, poorly understood.

Proteolytic dissection of SRP receptor

Using *in vitro* protein translocation assays as the principal tool, two different approaches³⁻⁸ eventually converged in the discovery and purification of the SRP receptor (or docking protein), as the first—and so far only—integral membrane protein known to play an essential part in this process of protein targeting. Proteolytic dissection of the SRP receptor gave a preliminary picture of its disposition in the ER membrane⁸. The bulk of its mass constitutes a cytoplasmic domain of relative molecular mass (M_r) 52,000 (52K) (see below; by SDS-polyacrylamide gel electrophoresis (PAGE) its size was previously estimated to be 60K) that can be severed from the membrane by a variety of proteases, and retains the ability to reconstitute the activity of proteolysed membranes. By itself, the cytoplasmic fragment—in contrast to the detergent-solubilized intact SRP receptor^{7,8}—is unable to release the SRP-induced arrest of presecretory proteins^{2,6}.

This finding raised the question of whether the 52K SRP receptor fragment still retains affinity for SRP. To directly examine this possibility, we mixed the 52K SRP receptor fragment with a fraction enriched in SRP receptor (Fig. 1, lane 1). We then applied this mixture to an SRP affinity column and monitored the elution of both the 52K SRP receptor fragment and the SRP receptor using Western blot analysis. Intact SRP receptor bound to the SRP affinity column and could be eluted with an increase in the magnesium concentration, as described previously⁹ (Fig. 1, lane 3). In contrast, the 52K fragment was only slightly retarded in the affinity column and was quantitatively recovered in the pooled flow-through and wash fraction (Fig. 1, lane 2). We conclude that the affinity of the 52K receptor fragment for SRP is greatly decreased compared with the intact receptor. Taken together, these findings suggest that the part of

Fig. 1 Chromatography of the SRP receptor and the 52K cytoplasmic fragment on SRP-Sepharose. Lane 1, load fraction; lane 2, combined flow-through and wash fractions; lane 3, column eluate. Arrows indicate the positions of the intact SRP receptor (A) and the 52K cytoplasmic fragment band (B), respectively. The asterisk denotes an additional minor breakdown product (~45K) that was contained in the 52K cytoplasmic fragment fraction.

Methods. SRP receptor was partially purified from canine pancreas following the procedure described elsewhere⁹, excluding affinity chromatography on SRP-Sepharose. The 52K cytoplasmic fragment was purified as described elsewhere². Both fractions were mixed to yield 600 μ l of a solution containing 350 ng SRP receptor and 300 ng 52K cytoplasmic fragment in buffer A (50 mM triethanolamine/HOAc pH 7.5, 20 mM KOAc, 5 mM Mg(OAc)₂, 250 mM sucrose, 0.5% octaethyleneglycol-mono-*n*-dodecyl ether (Nikkol; Nikko Chem. Corp., Tokyo, Japan), 1 mM dithiothreitol) and 15 mM NaH₂PO₄. The mixture was applied to a 150- μ l SRP-Sepharose column (containing 40 μ g coupled SRP). The binding capacity of this column was empirically determined to be in excess of 1 μ g SRP receptor bound per 150 μ l of resin. The column was washed with 600 μ l of buffer A containing 50 mM KOAc and eluted with 450 μ l of buffer A containing 10 mM KOAc and 25 mM Mg(OAc)₂. Fractions corresponding to 10% of the load were precipitated with trichloroacetic acid and subjected to SDS-PAGE. The gel was blotted onto nitrocellulose. SRP receptor and the 52K cytoplasmic fragment were detected by incubation with a monoclonal antibody against SRP receptor (V. Rath and P.W., to be described elsewhere) followed by incubation with iodinated second antibody and autoradiography²¹.

the SRP receptor that remains membrane-associated after proteolysis does not only contain sequences required to anchor it in the ER membrane, but must also contribute to a functionally important domain of the intact receptor.

Protein sequencing

Clearly, knowledge of the primary sequence of the SRP receptor would help our understanding of its structural organization. We therefore purified SRP receptor and the 52K SRP receptor

above), (2) nucleotide 1,403 (T in λ SR31 and λ SR63, C in λ SR32; a conservative change) and (3) one of the eight nucleotides (G in λ SR31 and λ SR63, C in λ SR32) which was found to be deleted in λ SR32 and λ SR63. We attribute these latter discrepancies to errors of reverse transcriptase during the cDNA synthesis. The triangles in the restriction map indicate the beginning and end of the cDNA sequence used for the synthesis of the complementary DNA and predicted amino-acid sequence of the SRP receptor. Linker sequences have been omitted. The amino-terminal of the intact receptor (a) and the cytoplasmic fragment (b) are underlined. The region preceding Met 1 translates into Leu-Pro-Ala-Ala-Ala (-1). The polyadenylation signal, AATAAA, is boxed.

fragment from canine pancreas as described previously^{2,7}. Following preparative SDS-PAGE as an additional purification step, the proteins were eluted electrophoretically from the gels and subjected directly to sequence analysis on a gas-phase sequencer. Neither of the polypeptides appeared to be blocked at their amino termini and we were able to determine the first 24 amino acids of the SRP receptor and the first 10 amino acids of the 52K SRP receptor fragment (see Table 1). From these data, we concluded first that the SRP receptor and the 52K SRP receptor fragment have different amino termini, and second that the 52K SRP receptor fragment has a unique sequence which indicates that elastase—the protease used to sever this domain from the membrane—cleaves the SRP receptor in a unique position.

cDNA cloning

Knowledge of the partial primary sequences of these polypeptides allowed us to identify cDNA clones of the SRP receptor. According to codon usage frequencies¹⁰, we designed a single 48-nucleotide(nt)-long double-stranded DNA probe coding for the first 16 amino acids of the receptor (Fig. 2A) and used it to screen a cDNA library in phage λ gt10, constructed by oligo(dT)-priming of canine pancreatic poly(A)⁺ RNA (see Fig. 2 legend). From the library (containing ~500,000 clones), we isolated one recombinant phage (λ SR1, Fig. 2) that gave a strong hybridization signal and which contained an insert of 805 base pairs (bp). Re-screening of the library with this cDNA insert (see Fig. 2 legend for experimental details) did not yield any new cDNA clones, indicating that the isolated clone was the only

Fig. 3 Northern blot analysis of poly(A)⁺ RNA from MDCK cells (lane 1), canine kidney (lane 2), liver (lane 3), testis (lane 4) and pancreas (lane 5).

Methods. Total cellular RNA was prepared by the guanidine monothiocyanate/LiCl precipitation method²⁴ and selected on oligo(dT)-cellulose²⁵; 3.3 μ g (lanes 1–4) or 6 μ g (lane 5) of RNA was separated in a 1.2% agarose/formaldehyde gel²⁵ and transferred directly to nitrocellulose. Hybridization conditions were exactly as described in Fig. 2 legend using the insert of clone λ SR31 as probe (5×10^8 c.p.m. μ g⁻¹, 1.5×10^6 c.p.m. ml⁻¹). The film was exposed for 3 days. The two additional bands in lane 5 are probably due to nonspecific interaction of the probe with 18S and 28S ribosomal RNA; the relative proportion of these RNA species as visualized by ethidium bromide staining was higher in the pancreatic preparation than in the other lanes.

Table 1 Sequence analysis of the SRP receptor and the 52K SRP receptor fragment

Cycle	SRP receptor		52K cytoplasmic fragment

24	Ser	4		

Both proteins were purified from canine pancreas as previously described^{2,9}. After preparative PAGE in SDS using a 7–11% gradient gel and electroelution²², the samples were applied directly to sequencer filters precycled with 1.5 mg of Polybrene. Sequence analysis was performed in a gas phase sequencer (Applied Biosystems model 470 A). The phenylthiohydantoin amino acids were separated using a Waters HPLC system equipped with a Rainin Microsorb C8 column (0.46 \times 25 cm) heated to 45 °C in a gradient of solvent I [0.25 M NaH₂PO₄ pH 4.6/CH₃CN/H₂O (10/18/72 by volume)] to solvent II [H₂O/CN₃CN (70/30)]. Initial yields were 88% and 40%, average repetitive yields amounted to 94% and 93% for SRP receptor and 52K cytoplasmic fragment, respectively. Protein determinations were performed by densitometric scanning of Coomassie blue stained bands in analytical SDS polyacrylamide gels using bovine serum albumin as a standard.

one containing these SRP receptor sequences. We therefore constructed further cDNA libraries from poly(A)⁺ RNA from MDCK (Madin Darby canine kidney) cells. Screening of these libraries (containing 500,000 recombinant clones) yielded four additional overlapping clones (λ SR31, 32, 50 and 63; schematically described in Fig. 2B) which cover the complete coding and 3'-untranslated sequence of the SRP receptor (see below).

We estimate that the SRP receptor constitutes only 0.1% of the protein contained in a rough ER cell fraction from pancreas. This low abundance, together with the fact that pancreatic messenger RNA largely encodes secretory and not cellular 'household' proteins, could account for the scarcity of SRP receptor sequences in this library. Indeed, in a Northern analysis of poly(A)⁺ RNA isolated from different canine tissues (Fig. 3), the relative abundance of SRP receptor transcripts was substantially higher in tissues with lower secretory activity. The best signal was obtained with RNA from MDCK tissue culture cells, presumably because a rapidly dividing cell is forced to constantly proliferate its ER membrane together with other vital cell functions.

Protein primary sequence

Analysis of the cloned cDNA sequence (2,931 bp) shows a single open reading frame that starts close to the 5' end. This reading frame contains a precise match with the amino-terminal amino-acid sequence of the SRP receptor extending beyond the amino acids used to design the oligonucleotide probe (Table 1, Fig. 2C). The predicted M_r of the encoded protein is 69,684, in good agreement with its apparent M_r of 72K, as estimated previously by SDS-PAGE⁷. Amino-acid analysis of the purified protein yields values close or identical to those derived from its predicted primary structure (data not shown). The cloned DNA extends for 41 nucleotides to the 5' side of the sequence coding for the amino terminus of the SRP receptor. Because this sequence does not contain an in-frame stop codon, we cannot formally exclude the possibility that the SRP receptor could be encoded as a precursor containing a cleavable signal sequence preceding Met 1. However, translation of these nucleotides (see legend to Fig. 2C) does not result in an amino-acid sequence resembling that commonly found in signal peptides¹¹. Therefore, it is possible that—as is the case for other integral membrane proteins (see ref. 12)—the information required for its integra-

Fig. 4 Physical characteristics predicted from the SRP receptor primary structure. **A**, The locations of the membrane-anchoring fragment and the cytoplasmic domain extending to the carboxy terminus are indicated. Solid boxes mark the regions for which protein sequence data have been obtained; the vertical dashed line indicates the elastase cleavage site. **B**, Hydrophobicity values³³ were averaged for windows of 14 residues and are given as kcal per mol per amino acid of average free energy for the transfer from a hydrophobic to a hydrophilic environment. Regions I and II (amino acids 1–22 and 64–79, respectively) are candidates for sequence stretches interacting with the lipid bilayer. Clusters of charged residues are marked III (amino acids 84–97), IV (129–175) and V (205–243). **C**, Charge distribution along the SRP receptor sequence. All histidine, arginine and lysine residues were assumed to be positively charged (upward-projecting lines) and glutamic and aspartic acid residues to be negatively charged (downward-projecting lines).

tion into the membrane is encoded in an uncleaved signal sequence which in the SRP receptor would be contained in the amino-terminal portion of the protein (see below). The nucleotide context of the presumptive initiating ATG codon (GXXATGY) is also found in other eukaryotic mRNAs¹³, although it diverges from the most commonly found consensus sequence, AXXATGG¹⁴.

The SRP receptor and the 52K cytoplasmic fragment were purified by different methods and monitored using different activity assays^{2,9}. Sequence alignment of the amino-terminal region of the 52K SRP receptor fragment reveals that the fragment begins with Met 152 of the intact receptor; this provides independent confirmation of the identity of the cloned sequence as SRP receptor cDNA. From the position of the amino terminus of the 52K cytoplasmic fragment within the sequence, we conclude that the amino-terminal 151 amino acids (calculated M_r 17.5K) comprise the membrane-anchoring fragment of the SRP receptor, and the remaining 487 amino acids (calculated M_r = 52K) comprise the cytoplasmic SRP receptor fragment. A schematic representation of the deduced amino-acid sequences of the SRP receptor and the 52K SRP receptor fragment is shown in Fig. 4A.

Fig. 5 Model of the disposition of the SRP receptor in the ER membrane. Regions I and/or II are the putative membrane-spanning regions; regions III–V contain the charge clusters described in the text. The arrow depicts the protease-sensitive site.

Analysis of the primary sequence for distribution of hydrophobicity reveals only two distinctly hydrophobic stretches (amino acids 1–22 and 64–79, labelled I and II in Figs 4B, 5) in the amino-terminal part of the sequence. These regions are, in principle, long enough to span the hydrophobic core of the membrane, although they are shorter than most known α -helical transmembrane segments¹⁵. However, either one or both of these regions must be in contact with the hydrophobic core of the lipid bilayer, because the intact SRP receptor can be released from the membrane only after its solubilization with detergents, and—according to the argument outlined above—it is anchored in the membrane through its amino-terminal 151 amino acids.

Apart from these two hydrophobic stretches, the remainder of the membrane-anchoring fragment of the SRP receptor is surprisingly hydrophilic. This character extends across the protease-sensitive site of the intact receptor for about 100 amino acids into the cytoplasmic fragment. In particular, the regions spanning amino acids 84–97, 129–175 and 205–243 show extreme hydrophilicity values (regions labelled III, IV and V in Figs 4B, C and 5) that are due to a remarkable abundance of charged amino acids (both basic and acidic in a relative proportion of ~2:1) which largely appear clustered (Fig. 4C). Notable is the predominantly basic character of these domains, which also dominates the overall charge of the SRP receptor (calculated pI = 9.86).

The remainder of the cytoplasmic portion of the SRP receptor contains periodically spaced regions, some of which exceed in length and hydrophobicity values those which must comprise the membrane anchor segment(s). However, as described above, on proteolysis the 52K SRP receptor fragment is readily released from the membrane, by treatment with high salt concentrations, as a rather stable and 'well-behaved' (that is, non-aggregating) soluble protein. Thus these hydrophobic stretches are probably buried within the protein. There remains the possibility that, during the functional cycle of the SRP receptor, these regions become transiently associated with the hydrophobic core of the lipid bilayer (see below).

Functional implications

When we compared the SRP receptor sequence with other known protein sequences, we found a striking resemblance of the mixed-charge amino-acid clusters (III–V in Fig. 4) to those regions in ribosomal proteins and aminoacyl-tRNA synthetases that are thought to be involved in binding of these proteins to RNA molecules^{16–19}. In addition, when the Dayhoff databank was searched for homologous protein sequences, the best match was found with sea urchin histone H1; there is 30% identity in an overlap extending from residues 120 to 201 of the SRP receptor, primarily due to the frequent occurrence of positively charged amino acids. The finding that regions III–V resemble nucleic acid-binding proteins raises the possibility that the SRP receptor could interact directly (through a domain constituted

by regions III, IV and/or V; indicated as a boxed region in Fig. 5) with the 7SL RNA in SRP, and thus become, albeit transiently, an integral part of SRP. Such a hypothesis is consistent with the fact that the SRP receptor can be eluted from an SRP affinity column (Fig. 1; ref. 9) with a relatively small increase in the magnesium concentration (from 5 to 25 mM), the ionic strength remaining constant. This small concentration difference is not likely to severely affect protein-protein interactions; however, the conformational state of RNA molecules is known to be highly dependent on the concentration of divalent cations²⁰. We therefore consider it likely that the mixed-charge amino-acid clusters III-V constitute or contribute to a domain in the molecule that is involved in its interaction with SRP. If these regions bind to the 7SL RNA molecule in SRP (as suggested by their primary structure), their separation by proteolytic cleavage (arrow in Fig. 5) could account for the apparent lack of activity of both the membrane anchoring fragment and the cytoplasmic fragment of the SRP receptor.

Bovine opsin has more than one signal sequence

Martin Friedlander & Günter Blobel

Laboratory of Cell Biology, Rockefeller University, New York, New York 10021, USA

By deletion of selected segments from a bovine opsin complementary DNA clone and subsequent analysis of transcripts in a cell-free translation-translocation system, we have localized two out of four theoretically conceivable signal sequences required for the integration of opsin into microsomal membranes.

THE *in vitro* translation of messenger RNAs for integral membrane proteins in the presence of an appropriate acceptor membrane (representing the *in vivo* site of integration) has proved to be a useful approach for studying the mechanism by which proteins are asymmetrically integrated into membranes.

Experiments of this kind were first carried out using glycoprotein G of the vesicular stomatitis virus as a model integral membrane protein and dog pancreas microsomal membranes as a model acceptor membrane¹⁻³. These experiments suggested that the initial events in the integration of the G protein into microsomal membranes were similar to those that occur in the translocation of secretory proteins. In both cases, the proteins were synthesized with transient amino-terminal signal sequences that were cleaved during or shortly after translocation³. Moreover, the signal sequences of these two proteins were similar and used the same translocation machinery in the microsomal membrane³. Translocation, as well as integration, was shown to be dependent on the signal recognition particle (SRP): translocation (integration) did not occur with KCl-washed (SRP-depleted) microsomal membranes (KRM) and the re-addition of SRP restored this ability (for summary, see ref. 4).

Several proteins that are not synthesized as larger precursors and therefore do not have cleaved signal sequences have been studied using the above assays. Two different integration

mechanisms could be distinguished experimentally⁵⁻¹⁰. In one case, exemplified by cytochrome *b₅*, integration into the lipid bilayer occurs spontaneously and independently of SRP⁵⁻⁸. The segment within the protein that specifies such spontaneous insertion into membranes has been termed an 'insertion' sequence¹¹. In the other case, exemplified by Ca²⁺-ATPase⁸, integration is specified by a signal sequence and is catalysed by SRP.

The present study used bovine opsin as a model for integral membrane proteins that are not synthesized as larger precursors and are polytopic¹¹. Opsin traverses the membrane seven times, resulting in four separate hydrophilic domains being exposed on the exoplasmic side of the microsomal membrane and four on the cytoplasmic side (for summary, see refs 12, 13). We shall call 'trans' domains those portions of the molecule that have been translocated across the membrane such that they extend into the microsomal vesicle lumen (representing the 'outside' of the cell). Those portions that are not translocated across the microsomal membrane and remain in the biosynthetic compartment of the cell are called 'cis' domains. Hypothetical considerations¹¹ indicate that several possible mechanisms could establish this topology. For example, each of the translocated domains may require a separate signal sequence. If this were the case, opsin may contain as many as four uncleaved signal sequences, one for each domain to be translocated. Alternatively, a single

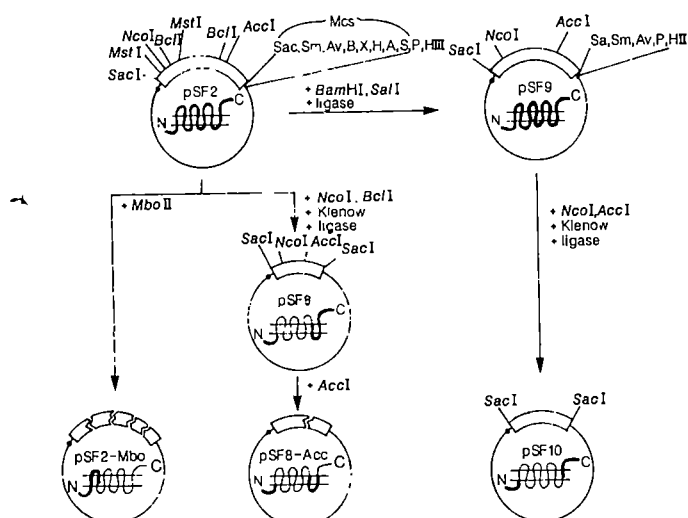

Fig. 1 Construction of opsin-containing SP6 vectors. Mcs, multiple cloning site; Sac, *SacI*; Sm, *SmaI*; Av, *AvaI*; B, *BamHI*; X, *XmaI*; H, *HincII*; A, *AccI*; S, *SalI*; P, *PstI*; HIII, *HindIII*; N, amino-terminus; C, carboxy-terminus; solid circle, SP6 polymerase binding site. A schematic representation of the various forms of opsin encoded by each plasmid is included within each large circle. The two parallel lines represent the membrane lipid bilayer and the opsin molecule is depicted by a waveform that traverses the membrane seven times. The darkened portion of each opsin represents the portion of the molecule encoded by the respective plasmids.

Methods. A cDNA clone (bd20) encoding the entire opsin apoprotein of bovine rhodopsin was obtained from Dr J. Nathans (Stanford University)¹⁴. This 1,639-nucleotide clone was removed from pBR322 by cutting it with *SacI* and ligating the resulting 1,382-base pair (bp) restriction fragment into the *SacI* site of Sp65 (ref. 17). This plasmid (pSF2) was used to transform a *dam*-methylase⁺ strain of *Escherichia coli*, GM48. The insert contained nucleotides 36–1,414 of bd20, 60 nucleotides of the 5'-untranslated region, a coding region of 1,044 nucleotides and 274 3'-untranslated nucleotides. pSF2 was used to prepare various truncation or deletion recombinants. All cloning procedures were as described by Maniatis *et al.*²⁸ and restriction digests were carried out in conditions recommended by New England Biolabs. Recombinant plasmids, as described below, were identified by restriction endonuclease digestion and used to synthesize mRNA¹⁷. Construction of specific plasmids: pSF2-Mbo. This truncated form of opsin (encoding amino acids 1–93) was obtained by digesting pSF2 with *MboII*. Multiple fragments were generated, but only one 710-bp piece contained the SP6 polymerase binding site continuous with the first 311 nucleotides of the opsin insert. pSF8. To obtain this plasmid, pSF2 was digested with *NcoI* and *BclI*. The resultant 3' recessed termini were filled-in with Klenow fragment and ligated to produce a recombinant with the correct opsin reading frame, a retained *NcoI* site and no *BclI* site. pSF8-Acc. This truncated DNA, prepared by digesting pSF8 with *AccI*, encoded a 79-residue protein. pSF9. Identical to pSF2 except that 8 nucleotides of the SP65 multiple cloning site were deleted by digesting pSF2 with *BamHI* and *SalI* and re-ligating the linearized vector. This was done to remove the *AccI* site from the multiple cloning site so that the *AccI* site at nucleotide 961 in the opsin coding region became a unique restriction site. pSF10. This plasmid encodes 83 amino acids of opsin, including the 34 amino-terminal residues continuous with, in frame, the carboxy-terminal 48 residues. An additional Cys residue at position 35 is a result of filling-in and ligating. Thus, a form of opsin is obtained which contains none of the transmembrane segments and only the first *trans* and the last *cis* domains. To obtain pSF10, pSF9 was digested with *NcoI* and *AccI*, filled-in with Klenow and ligated, resulting in the loss of the *NcoI* and *AccI* sites and the acquisition of an additional *NlaIII* site.

signal sequence may be used for the translocation of the NH₂-terminal translocated domain (which is glycosylated at two sites) followed by three insertion sequences, one each for the three remaining translocated domains. Combinations of signal and insertion sequences (one for each translocation domain) are also conceivable. Finally, it is possible that opsin does not contain signal sequences and that its integration occurs exclusively by insertion sequences.

To distinguish between these possibilities and to localize at least some of the 'topogenic' sequences required for integration¹¹, we carried out manipulation at the DNA level, either by truncating a full-length complementary DNA clone of bovine opsin¹⁴ or by cutting the cDNA clone and ligating various segments of interest. The resulting constructs (as well as the uncut full-length cDNA) were then transcribed and the RNAs

Fig. 2 Opsin is integrated into microsomal membranes in an SRP-dependent fashion. SP6-generated opsin mRNA¹⁷ and total rabbit reticulocyte RNA were translated in a wheat-germ system with (+) or without (–) SRP (800 U ml^{–1}) or salt-washed membranes (KRM, 2 µl) in a total reaction volume of 24 µl. In lanes 9 and 10, the stars indicate that KRM were present only during extraction with alkali, not during translation. Following translation, samples in lanes 5–12 were treated with alkali (pH 11.0) for 10 min on ice, centrifuged into an alkaline sucrose cushion for 10 min at 30 p.s.i. in a Beckman airfuge and then separated into supernatant (S) and pellet (P) fractions before solubilization and gel loading. The samples in lanes 13 and 14 were immunoprecipitated with antiserum to opsin and then prepared for SDS-PAGE. In lane 15, the sample was treated with Endo H (E) and then immunoprecipitated with anti-opsin serum. OP, primary translation product of opsin; GLO, α and β-globin; IP, immunoprecipitates; alkali, alkali-extracted. Downward-pointing arrows indicate the position of the glycosylated form of opsin.

Methods. Sp6-generated mRNAs were prepared from linearized plasmids (see Fig. 1) as described by Melton and co-workers¹⁷. After transcription, mRNAs were purified by phenol/chloroform extraction and ethanol and then lithium precipitation²¹. The wheat-germ *in vitro* translation system has been described previously¹⁸; 60 or 100 ng of pSF2 mRNA and 20 A₂₆₀ U of total rabbit reticulocyte RNA were added to each 24-µl reaction mixture. Translations were carried out for 40–60 min at 23 °C and stopped by chilling on ice and precipitation with an equal volume of cold 20% trichloroacetic acid. Preparation of KRM and SRP was as described previously^{29,30}; 2 µl KRM was used with 20 U SRP for each 24-µl translation mixture. Alkali extraction and alkaline sucrose gradient centrifugation were carried out according to Gilmore and Blobel²³. Digestion with Endo H was for 12 h as described previously³¹. The SDS-PAGE system has been described elsewhere¹⁶.

translated in a wheat-germ cell-free translation system in the presence or absence of SRP-depleted microsomal membrane and/or the absence or presence of SRP. Our data suggest that opsin contains at least two signal sequences.

Opsin integration requires SRP

Our first objective was to determine whether full-length opsin, which is not synthesized as a larger precursor¹⁵, contains a signal sequence or whether its integration into microsomal membranes¹⁶ is mediated entirely by insertion sequences. A construct of full-length opsin DNA in SP6 (pSF2; see Fig. 1) was transcribed¹⁷ and the RNA translated in a wheat-germ cell-free system¹⁸. Rabbit reticulocyte RNA (coding primarily for the two globin chains) was included in all translations (unless otherwise noted). The synthesized globin served as an internal

control, as its synthesis should not be affected by SRP and it should not be integrated into microsomal membranes. Opsin and the two globin chains (the latter were not resolved from one another) were indeed the major translation products (Fig. 2, lane 1). Addition of 20 units of SRP caused inhibition of opsin synthesis without affecting the synthesis of globin (Fig. 2, lane 2). These data suggested that opsin contains a signal sequence which, by analogy to the cleaved NH₂-terminal signal sequences of secretory proteins¹⁹, caused an SRP-mediated elongation arrest. A discrete arrested fragment (or several discrete fragments if there are several signal sequences) has so far not been detected.

More definitive evidence for the existence of a signal sequence in opsin was the synthesis of a glycosylated form of opsin in the presence of SRP and KRM (SRP-depleted membranes) (Fig. 2, lane 4, downward-pointing arrow). As expected, this glycosylated form was sensitive to treatment with endoglycosidase H (Endo H) (Fig. 2, compare lanes 14 and 15). The synthesis of a glycosylated form of opsin indicated that at least the NH₂-terminal domain of opsin was translocated. Note that the glycosylated form of opsin was synthesized only when both KRM and SRP were present. In the absence of SRP only the non-glycosylated form was synthesized (Fig. 2, lane 3). The SRP-mediated inhibition of opsin synthesis was largely abolished in the presence of KRM (Fig. 2, compare lane 2 with lanes 3, 4). These data are consistent with release of an SRP-mediated elongation arrest by KRM¹⁹.

Although the SRP-dependent appearance of a glycosylated form of opsin suggested a signal sequence-mediated mechanism of translocation (at least for the glycosylated NH₂-terminal domain of opsin), it was conceivable that the three *trans* domains further downstream were integrated by insertion sequences (for example, independently of SRP). In this case, the non-glycosylated opsin synthesized in the presence of KRM only (Fig. 2, lane 3) might also be integrated. As a criterion for integration, we used non-extractability at alkaline pH (pH 11)^{8,20}. When synthesized in the absence of SRP, the non-glycosylated form of opsin was not integrated into KRM, as >90% was extracted by alkali (Fig. 2, compare lanes 5 and 6). The small amount of opsin that was resistant to alkali extraction was not integrated into KRM, but, rather, represented aggregated material co-sedimenting with KRM. This aggregated material was observed even when KRM and NaOH were added together (Fig. 2, lanes 9, 10) or when KRM were omitted altogether (Fig. 2, lanes 11, 12). Thus, it appears that insertion sequences are not used for the integration of opsin. However, these data alone do not exclude the possibility that translocation of the NH₂-terminal domain of opsin by a signal sequence is required for the subsequent expression of putative insertion sequences that may serve to integrate the other three translocated domains.

As expected, the glycosylated form of opsin synthesized in the presence of SRP was not extracted at alkaline pH (Fig. 2, compare lanes 7 and 8). In addition, when synthesized in the presence of SRP, a significant amount of the non-glycosylated form of opsin was resistant to alkali extraction. This non-glycosylated, non-extractable form of opsin probably represented opsin that had been integrated but not glycosylated. This could be a result of an inefficiency of dog pancreas microsomal membranes to glycosylate relative to their ability to translocate. Alternatively, if opsin possesses separate signal sequences for each translocated domain, the first one (responsible for translocation of the first *trans* (glycosylated) domain) might have been missed, yielding non-glycosylated opsin integrated via any or all of the other signal sequences. Note that all of the globin chains were completely extracted by alkali in any of the experimental conditions used (Fig. 2, lanes 5–12) and thus behaved as predicted for a non-integrated, cytoplasmic protein. Although resistance to alkali extraction does not prove that glycosylated opsin was integrated correctly (that is, with all four *trans* domains properly translocated), we can conclude that this was the case for at least the first *trans* domain, containing the two glycosylation sites.

Fig. 3 The first 93 amino-terminal residues of opsin contain a signal sequence. pSF1 was digested with *Mbo*II and the resultant truncated plasmid (pSF2-Mbo) was used to generate mRNA translated in the wheat-germ system with (+) or without (-) SRP or KRM as described in Fig. 2 legend. The samples in lanes 5–8 were treated with alkali as described in Fig. 2 legend. The translation products in lanes 9–11 were immunoprecipitated with anti-opsin serum and those in lane 11 were treated with Endo H and then immunoprecipitated as described in Fig. 2 legend. Due to overexposure of this autoradiograph, the inhibition of synthesis of pSF2-Mbo is not readily apparent. When the globin and pSF2-Mbo bands were cut and quantitated¹⁹, the globin band in lane 1 contained 162,000 c.p.m. and that in lane 2 contained 171,000 c.p.m.; for pSF2-Mbo, these counts were 236,000 (lane 1) and 138,000 (lane 2). After correcting the pSF2-Mbo values for sample variability¹⁹, it was calculated that pSF2-Mbo synthesis was inhibited by 63% in the presence of SRP.

Localization of opsin signal sequence

Our initial strategy to localize the signal sequence was to determine the minimum length of opsin necessary for integration. The opsin-containing SP6 plasmid was cut with various restriction enzymes to generate a number of truncated opsins consisting of progressively shorter NH₂-terminal ends of the molecule. The shortest truncated form, pSF2-Mbo, encoded the 93 NH₂-terminal amino acids of opsin (calculated relative molecular mass (*M*_r) 12,300), and consisted of the first *trans* domain, the first transmembrane segment, the first *cis* domain and most of the second transmembrane segment. Translation yielded a product of the expected mass (Fig. 3, lane 1). Translation was inhibited in the presence of SRP (Fig. 3, compare lanes 1 and 2). Moreover, a glycosylated form of the 93-residue translation product was synthesized only in the presence of both KRM and SRP (Fig. 3, lane 4, downward-pointing arrow), not with KRM alone (Fig. 3, lane 3). As expected, the glycosylated form was not extracted by alkali (Fig. 3, compare lanes 7 and 8), whereas the non-glycosylated form synthesized in the absence of SRP was extracted (Fig. 3, compare lanes 5 and 6). The non-glycosylated and glycosylated forms of this polypeptide could be immunoprecipitated with an antiserum against a synthetic peptide representing residues 14–23 of opsin (Fig. 3, lanes 9–11). Furthermore, the glycosylated form was sensitive to Endo H digestion (Fig. 3, lane 11).

These data suggest that a signal sequence is localized in the first 93 residues of opsin. Of these, 30–40 carboxy-terminal residues can be expected to be sequestered in the ribosome^{21,22}. As the signal sequence is presumably expressed only when exposed on the surface of the ribosome¹⁹, the 30–40 carboxy-terminal residues of the 93-amino-acid polypeptide (which

Fig. 4 The amino-terminal *trans* domain of opsin does not function as a signal sequence. A form of opsin containing only the amino-terminal 34 residues fused to the carboxy-terminal 37 residues (encoded by pSF10) was analysed for SRP-dependent integration and translocation. Reticulocyte RNA was omitted from the translation mixture because the proteins encoded by pSF10 and globin have similar electrophoretic mobilities (data not shown). pSF9-10 (300 ng) was used to programme the wheat-germ translation system in the presence (+) or absence (-) of KRM and SRP as described in Fig. 2 legend. The samples in lanes 5-8 were treated with alkali as described for Fig. 2.

include the second transmembrane segment and much of the first *cis* domain) could therefore not have served as a signal sequence. Thus, the first 53-63 residues (comprising the first *trans* domain and the first transmembrane segment) must contain the potential sites for a signal sequence.

To determine which of these two domains might contain a signal sequence, we constructed a plasmid (pSF10) in which most of the first *trans* domain was ligated to the fourth *cis* domain (the latter is highly charged and is not expected to contain a signal sequence). Since the translation product of this construct (calculated M_r 10,630) co-migrated with the globin chains (data not shown), reticulocyte RNA was omitted from the translation. The data shown in Fig. 4 indicate that this construct does not contain a signal sequence: there was no significant SRP-mediated inhibition of translation (Fig. 4, compare lanes 1 and 2), no SRP-mediated appearance of a glycosylated form (Fig. 4, compare lanes 3 and 4), and no SRP-mediated alkali-resistant integration (Fig. 4, compare lanes 5-8). We therefore conclude that a signal sequence is not localized in the region of the glycosylated *trans* domain, but, rather, in the region comprising the first transmembrane segment.

A second signal sequence

As discussed above, opsin could contain as many as four signal sequences, one for each domain to be translocated. To localize a second signal sequence, we ligated the DNA encoding the first *trans* domain to that encoding a carboxy-terminal portion of opsin beginning with the sixth transmembrane segment (Fig. 1). The transcribed RNA of this construct (pSF8) yielded a translation product with a predicted M_r of 16,500. It is clear that this opsin construct contains a signal sequence (Fig. 5a). Its translation was inhibited by SRP. Moreover, the synthesis of a glycosylated form (Fig. 5a, lane 4, downward-pointing arrow) that resisted alkali extraction was dependent on the presence of SRP (Fig. 5a, compare lanes 1-4). As neither the amino-terminal *trans* domain nor the carboxy-terminal *cis* domain contains a signal sequence (see Fig. 4), the signal

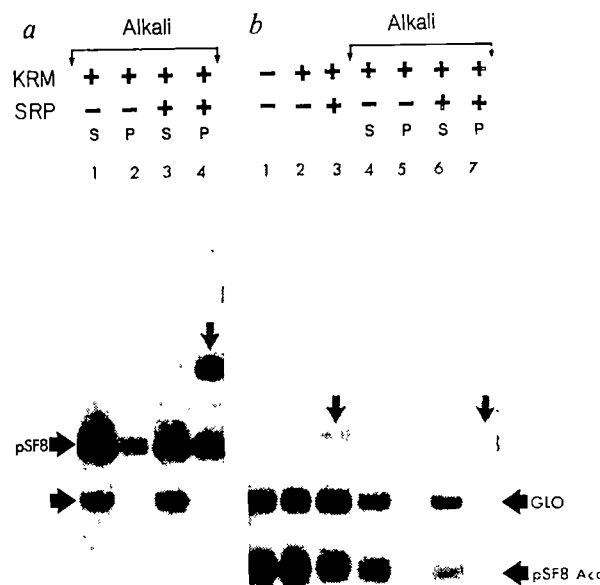

Fig. 5 A second signal sequence is located in the sixth transmembrane segment. *a*, An opsin construct (pSF8) containing the first and fourth *trans* domains, transmembrane segments VI and VII and the fourth *cis* domain, was analysed for SRP-dependent integration and translocation. pSF8 (150 ng) was used to programme the wheat-germ translation system in the presence (+) or absence (-) of KRM or SRP as described in Fig. 2 legend. Following translation, the samples were alkali-treated as described for Fig. 2. *b*, A truncated form of pSF8 (pSF8-Acc) (encoding the first *trans* domain, sixth transmembrane segment, *trans* loop 4 and 14 residues of the seventh transmembrane segment) was used to programme the wheat-germ translation system and the translation product was analysed for SRP-dependent integration and translocation as described for *a*. Following translation, the samples displayed in lanes 4-7 were extracted with alkali as described for Fig. 2. The glycosylated forms (downward-pointing arrows) were Endo H-sensitive (data not shown).

sequence of this construct must be localized in a region comprising transmembrane segments 6 and 7.

To localize the signal sequence more precisely, we prepared a truncated form of this construct (pSF8-Acc), resulting in the removal of the fourth *cis* domain and part of the seventh transmembrane segment. Of this translation product, 30-40 of the carboxy-terminal residues would not be exposed on the ribosome and therefore could not function as a signal sequence. Thus, if this construct contains a signal sequence, it must be localized in the sixth transmembrane segment, specifically in the amino-terminal portion of this segment. Figure 5b shows that a signal sequence was, in fact, present in this construct. A glycosylated form (Fig. 5b, lanes 3, 7, downward-pointing arrows) was synthesized only in the presence of SRP and was resistant to alkali extraction (Fig. 5b, compare lanes 4-7). We emphasize that although these data show the presence of a signal sequence in the amino-terminal portion of the sixth transmembrane segment, our experiments do not rule out the possibility that the seventh transmembrane segment also has the potential to function as a signal sequence.

In the two cases (Figs 3, 5b) where we have used truncated forms of opsin (lacking a termination codon), we have analysed the translation mixture by sucrose gradient centrifugation and subsequent SDS-polyacrylamide gel electrophoresis (PAGE) of gradient fractions. Surprisingly, in both cases ~60% of the truncated chains were released from the ribosomes (data not

Fig. 6 Model illustrating the possible locations of signal and stop transfer sequences within opsin. See text for explanation. N, amino-terminus; C, carboxy-terminus; Cis, cytoplasmic side of membrane; zigzag lines, signal sequences; thickened portion of line, stop transfer sequences; λ , glycosylation sites.

shown). As a result, the 30–40 carboxy-terminal residues of these released chains were no longer located within the ribosome and, thus, a signal sequence located within this region could potentially interact with the membrane. However, the recent demonstration²³ that signal sequences addressed to the endoplasmic reticulum (ER) can be expressed only when presented to the ER in the context of the ribosome (that is, only when the chain is attached to the ribosome) rules out the possibility that the observed integration was due to the expression of a signal sequence exposed after chain release.

Perspectives

The most important conclusion from our data is that the integration of a polytopic integral membrane protein with multiple translocated domains may require multiple signal sequences. From hindsight, opsin turned out to be a fortunate choice. Its first *trans* domain of 36 residues contains the only two glycosylation sites (at residues 2 and 15) of the protein. We showed that this domain does not function as a signal sequence. In the deletion experiments described above, the first *trans* domain could always be retained and therefore be used as a convenient 'reporter' domain in the search for signal sequences elsewhere in the molecule; the readily detectable glycosylation of this domain in the *in vitro* translation-translocation system indicated that translocation of this domain had taken place. By definition, whenever this translocation event was SRP-dependent, a signal sequence mediated the event. So far we have localized two signal sequences, one in the first transmembrane segment, the other in the amino-terminal portion of the sixth transmembrane segment. We assume that in full-length opsin the first of these would function in the translocation of the first (glycosylated) *trans* domain and the latter in the translocation of the fourth *trans* domain. Signal sequences are also likely to be used for translocating the second and third *trans* domains and might be located in the amino-terminal portions of transmembrane segments 2 and 4 (Fig. 6).

Among the important unresolved questions is the precise topology of the various constructs in the microsomal membrane. It is likely, however, that the first NH_2 -terminal *trans* domain, when glycosylated, is localized on the *trans* side of the membrane, since asparagine-linked glycosylation requires translocation²⁴.

Another unresolved question is how the signal sequence-induced translocation process (which goes to completion in the case of secretory proteins) is interrupted in the case of membrane proteins. One model proposes that a translocation is halted by a 'stop transfer' sequence which in turn triggers disassembly of a chain-conducting proteinaceous channel in the membrane¹¹. Alternative models propose that translocation is arrested by the interaction of hydrophobic stretches of the polypeptide chain with the lipid bilayer while the chain is passing across the bilayer (that is, the chain does not pass through a proteinaceous channel^{25,26}).

Figure 6 shows a scheme for the possible location of alternating signal and stop transfer sequences in opsin. The dynamics of the integration process could be envisaged within the framework of a previously proposed model¹¹. The interaction

of the first signal sequence with the membrane would proceed as described recently for secretory proteins (for summary, see ref. 4): the signal sequence, in the form of a loop^{26,27}, is recognized by SRP and a translation arrest is induced; the translation arrest is released by an interaction of the SRP with its cognate receptor (SRP receptor) in the ER, resulting in the displacement of SRP from the ribosome. These interactions bring the translating ribosome into the vicinity of the ER and would thus facilitate the subsequent interaction of the signal sequence with a putative signal receptor (which could be represented by signal peptidase) and of the ribosome with a putative ribosome receptor, both integral membrane proteins of the ER. The amino-terminal *trans* domain would then traverse the membrane through the proteinaceous channel (which might be formed, at least in part, by the signal receptor and the ribosome receptor). The signal sequence would be displaced from its ER receptor following further chain elongation. Passage of the chain would eventually be interrupted by the appearance in the channel of a stop transfer sequence. As a result, the channel would open to the lipid bilayer and the first integrated transmembrane segment would, after lateral displacement, be entirely surrounded by lipid molecules. Further chain elongation would result in the extra-ribosomal exposure of the second signal sequence (again in the form of a loop) which would initiate a second round of translocation. A second stop transfer sequence would stop the translocation again. Two more rounds of translocation-initiation and translocation-termination would result in the proper topology for opsin. It is conceivable that SRP and its cognate receptor in the ER are involved only in targeting the first signal sequence to the membrane. The second, third and fourth signal sequences, in a shortened circuit, may be able to interact directly with the signal receptor in the membrane without first interacting with SRP. Although it is unknown whether such a shortened circuit (which bypasses recognition of the signal sequence by SRP and uses only the putative signal receptor in the ER) could occur *in vivo*, integration *in vitro* mediated by the fourth signal sequence (even though tested here separately and out of context) requires SRP.

Many of the predictions illustrated in our model (Fig. 6) can be tested. Thus, the two additional predicted signal sequences could be localized by experiments similar to those described here. Similarly, it may be possible to separate the signal sequences from the putative stop transfer sequences by designing constructs that retain one of the signal sequences, but none of the stop transfer sequences. Such constructs would be expected to be completely translocated.

The approaches used here may serve as a paradigm for determining which topogenic sequences (insertion sequences, signal sequences) are used for the integration of polytopic integral membrane proteins and precisely where within the protein these sequences are located.

We thank Dr Jeremy Nathans for providing us with a bovine opsin cDNA clone, Stephen deSanctis for synthesizing the opsin peptides used for immunization, Drs James Kaput and Reid Gilmore for many helpful discussions, Drs Susan Bock, Ann Erickson, Sheila Fallon, Brian Kay and Debkumar Pain for helpful comments, Gisele Nimic for preparing the illustrations, and the Departments of Medicine and Medical Education at the Hackensack Medical Center. This work was supported by the Alexandrine and Alexander L. Sinsheimer Fund, NIH grant EY05540 to M.F. and NIH grant GM27155 to G.B.

nature FIRST CONFERENCE IN JAPAN

◎ January 20 ⇒ 22, 1986

◎ Keio Plaza Hotel, Tokyo, Japan

Nature is pleased to announce a conference on the future of molecular biology and its applications in biotechnology and medicine, to be held at the **Keio Plaza Hotel, Tokyo**, on **January 20-22, 1986**. The conference will be addressed by distinguished molecular biologists from the United States, Europe and Japan.

The speakers from the United States will include Nobel Prize winners **James D. Watson** (*Cold Spring Harbor*), who (with F.H.C. Crick) first suggested the structure of DNA, and **Walter Gilbert** (*Harvard University*). Other speakers include: **Stanley Cohen** (*Stanford University*), **Tom Blundell** (*Birkbeck College, London*), **W.J. Peacock** (*CSIRO, Canberra*),

Walter Gehring (*University of Basel*)

Richard Lerner (*Scripps Clinic, La Jolla*)

Sydney Brenner (*Laboratory of Molecular Biology, Cambridge*)

Susumu Tonegawa (*Massachusetts Institute of Technology*)

Shosaku Numa (*Kyoto University*)

Tasuku Honjo (*Kyoto University*)

Ken-ichi Matsubara (*Osaka University*)

Yoshiki Hotta (*University of Tokyo*)

Mitsuaki Yoshida (*Cancer Research Institute*)

Tadatsugu Taniguchi (*Osaka University*)

Hisayuki Matsuo (*Miyazaki Medical College*)

Tokindo Okada (*National Institute for Basic Biology*)

Hal Weintraub (*Hutchinson Cancer Center, Seattle*)

The three main topics to be covered by the conference are

- Molecular biotechnology
- Development and regulation
- Immunology and virology

and the programme is being designed to provide an opportunity for those working in industry, medicine or academic research to bring themselves up to the forefront of research through discussion with world leaders. There will be ample time for questions and discussion. Simultaneous translation services into English and Japanese will be available.

Registration fees:
¥100,000

Radio emission from the jet and lobe of 3C273

R. J. Davis, T. W. B. Muxlow & R. G. Conway

Nuffield Radio Astronomy Laboratories, Jodrell Bank,
University of Manchester, Macclesfield, Cheshire SK11 9DL, UK

The 'superluminal' motion observed in the cores of radio sources such as 3C273 is now accepted^{1,2} as evidence of relativistic motion within a few parsecs of the centre, but it is less clear whether such speeds persist out to kiloparsec scales^{3,4}. The one-sidedness of such sources is often cited as evidence of relativistic Doppler beaming, but could equally be intrinsic. New maps of 3C273 at 151 and 408 MHz have been made using the MERLIN interferometer⁵, with dynamic range of $4 \times 10^3:1$ and $10^4:1$, respectively. These show that (1) there is an extended region or lobe to the south of the main jet, (2) the radio emission of the jet is continuous from the core to beyond the limit of the optical jet and (3) no counter-component can be found in the opposite direction to the jet. The ridge-line of the jet shows a 'wobble', the wavelength (λ) of which decreases by a factor of 6 along its length. We suggest a model in which the jet motion is relativistic throughout, the velocity decreasing from $\beta\gamma \approx 6$ to $\beta\gamma \approx 1$ (where β is the velocity and γ the Lorentz factor). Since the Doppler beaming factors calculated for this model are too small to hide the lobe or the head of a counter-component, we suggest that 3C273 is intrinsically one-sided.

The MERLIN interferometer⁵ was equipped for operation at 151 MHz in early 1985, and observations were made of 3C273 at this frequency on 1985 May 21. The resulting 151-MHz map at 3.0 arc s resolution is shown in Fig. 1 (the first MERLIN map to be published at this frequency), while Fig. 2 shows a 408-MHz map at 1.0 arc s resolution which was obtained by processing earlier observations⁶ using a new software procedure called MAP (R. G. Noble, A. Bailey and T.W.B.M., unpublished). This procedure, which uses the hybrid mapping method⁷, corrects both telescope errors and closure offsets in amplitude and phase. Furthermore, we have removed the effects of the confusing double source⁶, situated 8 arcmin away from 3C273. These techniques result in a considerable improvement in dynamic range. A 408-MHz map was also made at 3 arc s resolution (not shown) for comparison with Fig. 1.

The previously known features of the radio source^{3,6,8} are the flat-spectrum core coincident with the quasar, which is unresolved at 1 arc s resolution, and the steep-spectrum radio jet extending 22 arc s in position angle 222.5°, leading to a bright head. (The head contains three sub-components⁹ which are merged at 1 arc s resolution.)

An entirely new feature in Figs 1 and 2 is an extended low-brightness region on the southern side of the jet. By analogy with classical double radio sources, we refer to this feature as the 'lobe'. There is no trace of extended emission on the northern side to the limit of measurement. In Fig. 2 the lobe has a well-defined outline about halfway along the jet, but there is additional extended emission close to the side of the jet out to

Fig. 1 MERLIN map of 3C273 at 151 MHz with 3.0 arc s resolution. Peak brightness is 55.8 Jy per beam. Contours are at equal logarithmic intervals, two contours to a factor 2, above a bottom contour of 56 mJy per beam. Negative (dashed) contours are at -56 and -80 mJy per beam.

20 arc s, appearing to spread backwards from the head at an angle of about 20°. At the lower resolution of Fig. 1, the 151-MHz lobe emission is blended with that of the main ridge, but is more intense and more extended than at 408 MHz. The spectral index α_{151}^{408} (obtained by comparing the two maps at 3 arc s resolution) is 1.5 ± 0.3 in the lobe and 0.80 ± 0.05 in the jet. From consideration of the integrated spectrum, Foley and Davis⁶ showed that the low-frequency radiation must come from a hitherto undetected area some 50 (arc s)² in area. This value matches the area of the outermost contour in Fig. 1, and we suggest that the lobe accounts for most of the flux at frequencies < 20 MHz¹⁰.

The centre of the lobe is near the inner end of the optical jet, but there is no measured optical radiation from the lobe. (There is a blue extension on the north side¹¹, where there is no radio emission; this may be merely a coincidence.) The X-ray emission reported¹² as coming from the jet of 3C273 is also located near the inner end of the jet, and could arise in the radio lobe itself.

Both the morphology and the spectral index suggest that the lobe consists either of remnant material left behind after the passage of the active head, or of backflow. In either case, any motion will be slow, and the lobe emission will not be relativistically beamed. We have calculated physical parameters of the relativistic plasma in the lobe using standard formulae¹³, with $H_0 = 100 \text{ km s}^{-1} \text{ Mpc}^{-1}$, so that 1 arc s = 1.85 kpc. We assume the line-of-sight thickness to be 5 kpc. If as much kinetic energy is assigned to the positive ions as to the electrons in the plasma, the minimum pressure in the lobe is $10^{-10} \text{ dyn cm}^{-2}$, the equipartition magnetic field is $\approx 60 \mu\text{G}$, and the synchrotron lifetime at 151 MHz is $5 \times 10^6 \text{ yr}$. The lobe must be at least this

Fig. 2 MERLIN map of 3C273 at 407 MHz with 1.0 arc s resolution. Peak brightness is 13.5 Jy per beam. Contours are at equal logarithmic intervals, two contours to a factor 2, above a bottom contour of 6.75 mJy per beam. Negative (dashed) contours are at -6.7 and -9.5 mJy per beam. Positions in both Figs 1 and 2 have been calibrated by adjusting the position of the core to right ascension 12 h 26 min 33.248 s; declination +02° 19' 43.29" (VLA Calibrator list).

old if the steep spectral index indicates ageing. During this time, the head has moved forward some 10 arc s or 20 kpc, implying that the forward motion of the head is sub-relativistic, with a transverse component of velocity of the order of 0.01 c .

It might initially be supposed that the southward displacement of the lobe was caused by a transverse ambient 'wind' in the cluster of which 3C273 is a member¹⁴. However, the difficulty with this interpretation is that the ram pressure ρv^2 for the wind (where ρ is the ambient density and v the wind velocity) should be at least equal to the pressure in the lobe. If the wind velocity is of the order of 300 km s⁻¹, the required density corresponds to 10^{-1} H atoms cm⁻³. Such a high density is hard to reconcile with the radio polarization data¹⁵: the rotation measure of all parts of the source is ≤ 1.5 rad m⁻², and hence the integral $\int n_e B dl$ in front of the source is $\leq 10^{-6}$ cm⁻³ G pc (where n_e is the electron density, B is the magnetic field and l is the path length). There is thus an unresolved discrepancy, unless the ambient intergalactic gas is singularly devoid of magnetic field ($B < 10^{-10}$ G over 100 kpc).

In all previous pictures, both radio and optical, the core and jet have been separated by a gap of 10 arc s. The new maps show that the radio emission of the jet continues across the gap as a faint narrow ridge, unresolved in width (angle $\theta \ll 1$ arc s), and with brightness $\approx 10^{-3}$ of the peak. In the brighter part of the jet, the width of the ridge apparently increases, but this may be solely due to blending with the lobe. The ridge can be traced over the whole 21 arc s of length, and Fig. 3a shows the intensity profile at 408 MHz along the ridge-line, plotted logarithmically. The rise to the peak follows an exponential increase with an e-folding scale height of ≈ 2 arc s, or 4 kpc. Similar profiles are found at 151 MHz (Fig. 1) and also at 1.67 GHz⁶ and 5 GHz⁸, with little or no change in scale height. If this region were a trail, subject to synchrotron ageing as in the lobe, the scale height would vary as $\nu^{0.5}$. We suggest instead that the intensity profile indicates the rate at which energy is extracted from bulk kinetic energy and dumped into the synchrotron reservoir.

In Fig. 3b the position of the ridge-line is plotted relative to an axis through the core at position angle 222.5°. Close to the head, the pattern can be followed best at 1.67 GHz, and the last five points are taken from the $\lambda 18$ cm map at 0.35 arc s resolution⁶. The 'wobble' in the ridge-line^{3,6} is present throughout the

Fig. 3 a, Plot of intensity (log scale) along the ridge of the jet; b, deflection of ridge-line from a straight line through the core in position angle 222.5°. (The vertical scale is exaggerated $\times 5$.) ■, 408 MHz; *, 1,666 MHz.

length of the jet, superimposed on a centre-line which curves gently southwards by $\approx 2^\circ$ in position angle. The amplitude of the wiggle is constant, at about 0.5 arc s peak to peak, but the semi-wavelength of the pattern, measured between crossing-points, decreases systematically from 6 arc s to ≈ 1 arc s.

Wiggles are observed in many sources and have not been satisfactorily explained. However, the most straightforward interpretation of the systematic decrease in wavelength is as a deceleration of the jet material. If we interpret the wiggle in terms of precession in the central object with period T , the pattern wavelength λ is proportional to T and to the apparent transverse velocity β_{obs} :

$$\lambda = cT\beta_{\text{obs}} = cT\beta \sin \theta / (1 - \beta \cos \theta)$$

On this interpretation, the decrease of pattern wavelength down the jet indicates that deceleration begins at 10 arc s from the core, and continues to the head. The rate of deceleration thus mimics the rise in radio intensity. Because little braking is apparent in the inner part, we propose that the initial value of β_{obs} equals the superluminal value observed a few marc s from the core. The proper motion of 0.79 marc s yr⁻¹ (ref. 16) means that, if $H_0 = 100$ km s⁻¹ Mpc⁻¹, $\beta_{\text{obs}} = 4.8$ and T is 15×10^3 yr. Figure 3b then suggests that β_{obs} decreases to a value ≈ 0.8 at the point where the jet enters the head.

The degree of polarization observed at $\lambda 18$ cm in the brightest sub-component of the head⁹ has been explained in terms of relativistic aberration. If the Doppler blueshift factor is

$$\eta = (\gamma(1 - \beta \cos \theta))^{-1}$$

the aberration needed to account for the polarization (see ref. 9) requires that

$$\eta \sin \theta = \sin 47^\circ$$

By combining this value with the value of β_{obs} from the pattern wavelength, we may deduce the speed β and the angle θ of the motion near the head. If the value of θ does not change, parameters may also be obtained for the motion near the core.

Table 1 Model parameters for the motion in the jet reckoned in the frame of the observer

Region	Near core	Near head
Distance from core	≤ 10 arc s	21 arc s
Speed, β	0.987	0.74
Angle, θ	19°	19°
Lorentz, γ	6.2	1.5
Doppler blueshift, η	2.3	2.2
Apparent transverse velocity, β_{obs}	4.8	0.79
Factor $x = (1 + \beta \cos \theta) / (1 - \beta \cos \theta)$	28	5.5

Table 1 shows values for these quantities at each end of the jet, all values being expressed in the observer's frame of reference. The Lorentz factor of the initial velocity, when reckoned in the rest-frame of the quasar ($z=0.158$), is $\gamma \approx 7$.

The velocity model presented here is consistent with the radio data, but is not unique. In particular, the parameters could vary widely in value if the jet were bent, that is, if θ varied along the length. We note that a bend of position angle occurs at 8 marc s from the core¹⁶, and that most of the measurements of superluminal motion refer to distances less than 8 marc s. A crucial test of our model would be provided by measurement beyond the bend. According to the model, the proper motion should remain at $0.79 \text{ marc s yr}^{-1}$ at all points out to 10 arc s, decreasing to $<0.1 \text{ marc s yr}^{-1}$ near the head. Further measurements of the proper motion at high dynamic range and long wavelengths would help to resolve this question.

The observations presented here may be used to test whether or not the one-sidedness of 3C273 is due to Doppler beaming. The observed peak brightness in the head at 408 MHz is 13 Jy per beam at 1 arc s resolution, and 22 Jy per beam at 3 arc s. Identifiable sidelobes due to residual errors are present at the 30-dB level (1,000:1 down) north and south of bright features. Away from these points the r.m.s. noise level is 1.2 mJy per beam at 1 arc s resolution, or 1.9 mJy per beam at 3 arc s (these values are the observed r.m.s. values over several hundred square arc s in empty regions of the map, and are $\approx 50\%$ above the calculated thermal noise). Thus, the observed dynamic range at 408 MHz (defined as peak intensity per r.m.s. level) is $10^4:1$. At 151 MHz the corresponding values are 56 Jy per beam peak brightness, r.m.s. level 13 mJy per beam, giving a dynamic range of $4 \times 10^3:1$. Along the continuation of the major axis from the quasar out to the geometrical counter-head position 22 arc s away the 408-MHz map shows no emission above noise level, with a maximum value of 4 mJy per beam (2σ) near the geometrical counter-head.

We have calculated the intrinsic front/back ratio in luminosity for each component of the source, allowing for the Doppler beaming factors of any that are fast-moving. At the head the observed brightness at 3 arc s resolution is 22 Jy per beam, so that the observed head/counter-head ratio is $>5,500:1$. The expected brightness ratio for two equal jets in opposite directions is $x^{2+\alpha}$, where $x = (1 + \beta \cos \theta)/(1 - \beta \cos \theta)$. For the model suggested above with $\beta = 0.74$ and $\theta = 19^\circ$, the Doppler beaming ratio is 120. Even if the entire radiation from the head were beamed with this Doppler factor, the expected intensity from a counter-jet would be 190 mJy per beam, making the front/back ratio for the jet $\geq 47:1$. In practice the head almost certainly emits a mixture of beamed and unbeamed radiation. Flatters and Conway⁹ suggested that 1/6th of the head flux comes from a slow-moving precursor component with little beaming. The intrinsic front/back ratio on this basis is $\geq 1,000:1$.

The lobe emits at least 500 mJy unbeamed radiation at 408 MHz from an area of $15 (\text{arc s})^2$, while no region of equal area on the opposite side of the core emits more than 10 mJy. Thus, the observed front/back ratio for the lobe is $\geq 50:1$, in sharp distinction from classical double sources. While the high front/back ratios for the head are model-dependent, being based on our assumptions of jet speed, the front/back ratio for the lobe is free from such assumptions.

We conclude that there is no observational evidence of any counter-components in 3C273. Doppler beaming is insufficient to hide the counterpart of the lobe and probably that of the head. If such counterparts do exist, they must be intrinsically weaker than those observed by one or two orders of magnitude. Thus, 3C273 contains all the ingredients of a classical double source like Cygnus A, with core, jet, hotspots and extended lobe, but only on one side.

We thank R. A. Perley for data in advance of publication, and C. Flatters for useful discussions. The new high-quality maps were only made possible by software developed by R. G. Noble and A. Bailey on the new Starlink VAX node at Jodrell Bank.

Implications of ultra-high-energy emission from Hercules X-1

David Eichler

Astronomy Program, University of Maryland, College Park, Maryland 20742, USA and Department of Physics, Ben Gurion University, Beer Sheva, Israel

W. Thomas Vestrand

Physics Department, University of New Hampshire, Durham, New Hampshire 03824, USA

A 3-min outburst of very-high energy (VHE) quanta, $E > 10^{12} \text{ eV}$, was recently detected from the X-ray pulsar Hercules X-1 (ref. 1). The outburst occurred at a time during the 35-day X-ray modulation that is associated with X-ray turn-on. Temporal analysis of the outburst showed the same 1.24-s modulation that is observed at X-ray energies. Subsequent monitoring of the system at ultra-high energies (UHE) by the Fly's Eye² yielded evidence for a 40-min outburst of quanta with energies $E > 1 \times 10^{14} \text{ TeV}$. This UHE outburst also exhibited a 1.24-s modulation. Here we assume the quanta to be γ -rays and show how the interaction of these UHE particles with a precessing accretion disk can explain the observed γ -ray 'light' curve. We also discuss the possibility that the emitting UHE particles are accelerated by shocks in an accretion flow as well as the constraints that can be placed on the acceleration mechanism.

Hercules X-1 displays X-ray modulation with periods of 1.24 s, ~ 1.7 days and ~ 35 days^{3–5}. The simplest interpretation of the two shorter periodicities is that they are due to rotation and occultation of an accreting neutron star located in a close binary system^{3–7}. The unusual 35-day flux modulation has an X-ray light curve that is composed of an 11-day high-intensity state and a 19-day low-intensity state, interrupted midway between the 11-day high states by an intermediate high state (intensity $\sim 40\%$ of main high state) of 5 days duration^{3,4}. This modulation is usually referred to by the varying aspect of an inclined accretion disk that precesses about the X-ray pulsar^{5–7}. In this picture, the 19-day low state occurs when our view of the pulsar is obscured by the accretion disk and the 11-day high state occurs when our view is unobstructed. The intermediate high state occurs when our line-of-sight passes close to the disk and is partially obscured by the disk's corona.

An intriguing aspect of the high-energy observations is the phase at which the γ -ray outbursts occur during the 35-day X-ray modulation. The UHE outburst occurred on 11 July 1983 at phase $\phi_{35} = 0.63$ in the 35-day cycle². This epoch corresponds to the middle of the period, when the intermediate high state is normally observed. The VHE outburst occurred on 17 April 1983¹, the nominal time for the onset of the 11-day high-intensity state. Both outbursts occurred at a time when the accretion disk is situated so that our line-of-sight was grazing the disk.

An attractive explanation for these observations is provided by a particular variation in the class of beam dump models⁸ in which the accretion disk serves as the beam dump. It is related to the model we later proposed⁹⁻¹¹ for the reported post-eclipse emission of Cygnus X-3, which has also been applied to LMCX-4 (ref. 12). The model for Her X-1 assumes that UHE particles are accelerated in a co-rotating region near the pulsar and then stream outward to interact with the surrounding accretion disk. Energetic γ -rays will then be detectable when the beam of particles crosses our line-of-sight and interacts with a column thickness of material that is comparable to the particle's radiation length. A smaller thickness would be inefficient as a converter, whereas a larger column thickness would obscure the photons. In the Her X-1 system, this condition is usually best met at the onset and decline of the X-ray high states when our line-of-sight is grazing the precessing accretion disk. In fact, the VHE outburst did occur at the nominal time for the onset of the 11-day X-ray high state. However, the production of the UHE outburst during a phase normally associated with the centre of the secondary X-ray high state would require a thickening of the disk to yield sufficient target along our line-of-sight. The Exosat X-ray satellite observations of the source during the same period support this idea¹³. The satellite's failure to detect the X-ray high states, despite the continuing optical variability attributed to the reprocessing of X rays, led several authors^{13,14} to conclude independently that the disk was significantly thicker during this epoch.

The duty cycle of the UHE emission is only about 10% of the spin period², which we take to imply beaming of the UHE primaries.

We next consider the efficiency of particle acceleration in the Her X-1 system. The median energy of 500 TeV quoted by the Fly's Eye group² is based on the assumption that the γ rays have a power law spectrum. The apparatus in fact responded to γ rays $>1 \times 10^{14}$ eV (Elbert, J. W., personal communication). Taking, as a conservative estimate, the photon energies to be $E = 1 \times 10^{14}$ eV, a reported time-averaged UHE photon flux of 3×10^{-12} cm⁻² s⁻¹ (ref. 2) and a duty cycle of 0.1, we derive a peak UHE energy flux of 3×10^3 eV cm⁻². This should be compared with the total X-ray flux of 4×10^3 eV cm⁻². The conversion efficiency for UHE particles to photons is only $\sim 10\%$. A liberal estimate for the beaming factor can be made by assuming that the broadest part of the beam passes through our line-of-sight. The solid angle of the beam is then $\pi^3 \times 10^{-2}$, and the beaming factor is $\pi^2/4 \times 10^{-2}$. We conclude that the UHE particle luminosity is at least $\sim 25\%$ of the X-ray luminosity.

This sets strong constraints on models of particle acceleration. For example, acceleration scenarios¹⁵ that invoke the rotational energy of the accretion disk encounter the difficulty of that for Her X-1 parameters, which include a surface magnetic field of 4×10^{12} G, the inner radius of the accretion disk is located at more than 300 stellar radii. It is difficult to see how more than about 1/300th of the total energy budget could be channelled through rotation of the accretion disk. The fact that the UHE and VHE emission has the periodicity of the neutron star's rotation further supports the notion that the energy that goes into the UHE particles is liberated close enough to the neutron star for the in-falling material to co-rotate with it.

The high efficiency associated with shock acceleration makes it an attractive possibility for particle acceleration in the Her X-1 system. In particular, one expects a shock from the impact of the accreting material onto the star or its magnetosphere. Given that spontaneous injection occurs¹⁶, shock acceleration can take place¹⁷. It is not necessary for the shock to occur at the surface of the neutron star for the mechanism to put much of the released gravitational energy into UHE particles; all that is needed is that much of the pressure in the post-shock material that settles on the surface is in the form of UHE particles trapped in the flow. However, our understanding of shock acceleration enables us to place strong constraints on models that invoke it.

The synchrotron loss timescale for a particle of mass m , energy

$E_p = \gamma mc^2$ and charge Ze is given by

$$\tau_{sy}(E_p) = \frac{4\pi mc}{\gamma \sigma_T B^2} \left(\frac{m}{Z^2 m_e} \right)^2 \quad (1)$$

where B is the magnetic field strength in the region and σ_T is the Thompson cross-section. The time required to accelerate a relativistic particle to energy E_p is

$$\tau_a(E_p) = (\xi R_g) / (\beta_s c) \quad (2)$$

where R_g is the gyroradius ($R_g = \gamma mc^2 / (ZeB)$), ξR_g is the mean free path ($\xi \geq 1$) and $\beta_s c$ is the shock velocity. The maximum energy E_d to which a particle can be accelerated by a shock, even in the absence of synchrotron losses, is given by¹⁸

$$E_d = \frac{1}{\pi} \beta_s Z e B R \quad (3)$$

where R is the radius of the shock, which must be less than the size of the region. This limit comes from the fact that particles with energies greater than E_d can diffuse away from the system within the acceleration timescale. Stipulating that the acceleration must be faster than the synchrotron loss, and combining this limit with equation (3), we find that the maximum energy $\gamma_m mc^2$ to which a particle can be accelerated within a compact region of size R is given by

$$\gamma_m = \beta_s \left[\left(\frac{3}{2\pi\xi} \right) \frac{Rm}{Z^2 r_0 m_e} \right]^{1/3} \quad (4)$$

where r_0 is the classical electron radius.

If the shock velocity is taken to be the free fall velocity at a radius R from the neutron star, $V_{ff} = (2GM_*/R)^{1/2}$, then individual particle energies as high as $9 \times 10^6 mc^2 R_6^{-1/6}$ are possible (where $R = R_6 \times 10^6$ cm). This is sufficient to account for the UHE emission from Her X-1. Note also that this upper limit is rather pessimistic because it uses a classical equation for the synchrotron loss timescale. In fact, this loss rate is an overestimate when radiation reaction and quantum mechanical effects become important.

A final constraint, we note, is that the Alfvén Mach number of the shock must be high if much of the energy is to go into the highest-energy particles. That is

$$\rho_s u_s^2 \gg \frac{B^2}{8\pi} \quad (5)$$

where ρ_s is the preshock fluid density and u_s is $\beta_s c$. If ρ_s is fixed by the condition that

$$\rho_s u_s (\pi R^2) = \dot{M} = \frac{L}{(\epsilon c^2)} \quad (6)$$

where \dot{M} is the accretion rate, and is the conversion efficiency from accreted mass to luminosity L , this constrains the magnetic field to be less than $\beta_s^{1/2} L_8^{1/2} R_6^{-1/2} \times 10^8$ G, and R to be less than 10^8 cm. The synchrotron loss limit also constrains B to be less than $7 \times 10^{21} \xi \gamma_m^{-2}$ G. We see then that the model demands that the magnetic field within the accretion column be much less than the surface field of the neutron star. This is reasonable because the accreting material is a good conductor and is likely to pass between field lines of the neutron star on its way to the surface. However, it is not clear to what extent the flow retains its coherence between the magnetopause and the stellar surface. Alternatively, one could invoke a shock at 10-50 neutron star radii, where the field strength of the star's magnetosphere is 10^7 - 10^9 G.

We have proposed that the UHE emission reported from Her X-1 is generated by particles that interact with the surrounding accretion disk. The model predicts that high-energy γ -ray outbursts should occur preferentially at the onset and decline of the high-intensity X-ray states. The acceleration of the primaries occurs within the neutron star's magnetosphere, and the most obvious mechanism is acceleration by the accretion shock. A substantial fraction of the γ -rays may be generated within the

accretion column, the relative contribution of these two targets depending on the γ - γ opacity. Accretion-shock acceleration can account for the highest observed γ -ray energies, but not by a wide margin, and would be ruled out by detection of photons at 10^{16} eV or higher. Photons at $E > 10^{16}$ eV have been claimed by several authors, implying primary energies of $\sim 10^{17}$ eV (refs 12, 19). If these energy measurements are correct to within a factor of two, and if deep inelastic scattering behaves at these high energies as at lower ones, then according to our analysis, acceleration by accretion shocks cannot account for the primary energies. We emphasize the importance of precise energy measurements; γ -ray energies of $2\text{--}3 \times 10^{15}$ eV are marginally consistent with accretion-shock acceleration of the primaries. On the other hand, a shock created by a relativistic wind striking, say, an accretion disk at $R > 10^8$ cm, could generate primary energies of 10^{17} eV. Relativistic winds could result from supercritical accretion. It might be useful therefore, to search for correlations between E_{max} and evidence for relativistic winds.

Nitrogen oxides have a key role in the chemistry of the polluted and the unpolluted atmosphere^{1–4}. It has been proposed that important quantities of nitrogen oxides may be contained in the form of peroxyacetyl nitrate (PAN) especially in the colder regions of the middle and upper troposphere^{5,6}. Surface and aircraft observations of PAN have confirmed its ubiquity in the remote troposphere where it has been measured at mixing ratios of $10\text{--}500$ p.p.t.v. (parts per 10^{12} v/v) (refs 7, 8). To date, no study that is representative of the remote atmosphere has been made to assess directly the concentrations of PAN compared with that of the inorganic nitrogen oxides (NO and NO₂). Here we present the first study in which the mixing ratios of PAN, and nitrogen oxides—as well

as those of peroxypropionyl nitrate (PPN) and O₃ and relevant meteorological parameters—were measured concurrently at a location that receives clean, continental air. The results show that in clean conditions nitrogen oxides present in the form of PAN can be as much or more abundant than the inorganic form.

The measurements were made at the C-1 research site of the Mountain Research Station of the University of Colorado (40°2' N lat., 105°32' W long., 3.05-km elevation above sea level). Prevailing winds at this site are from the west and are relatively free of anthropogenic pollution. However, there are frequent occasions when winds from the east transport anthropogenic pollution to the site. The measurements, then, are representative of very clean to polluted conditions and must be interpreted in the context of the prevailing meteorology. This field study was conducted during the summer (1–16 July 1984; 24 August–2 September 1984) and the autumn (24 October–4 November 1984). The autumn period resembled early winter in that snow cover, high winds and low temperatures were typical.

The instruments used to measure NO_x, PAN and PPN, and O₃ have been described elsewhere^{9–11}. Briefly, NO was measured with a chemiluminescent technique and NO₂ was photolysed to NO before detection. The instrument has detection limits of 2 p.p.t. for NO and 10 p.p.t. for NO₂ based on a 10-s averaging time. The absolute accuracy of these measurements is estimated to be 15% for NO, 30% for NO₂ and 40% for NO_x. Unlike many instruments that catalytically reduce NO₂ to NO, the interference of PAN in the present NO₂ photolysis system was found to be <5% in laboratory tests^{9,10}. PAN and PPN were measured with two different instruments, both employing electron capture gas chromatography and cryogenic sample collection¹. Although the two PAN instruments did not operate concurrently, an intercomparison of results during similar atmospheric conditions indicated no systematic differences. With a 100 cm^3 (STP) sample the PAN, PPN instruments had a detection limit of ~ 5 p.p.t., a precision of $\pm 10\%$ and an estimated accuracy of 20–30%. O₃ was measured by a UV-absorption instrument (Dasibi, Inc., Model 1003-AH) with a detection limit of 3 p.p.b.v. (parts per 10^9 v/v) and an estimated uncertainty of $\pm 10\%$.

The relationship between the mixing ratios of PAN and NO_x are examined in Fig. 1. Summer and autumn data from two periods of the diurnal cycle are presented. First is an afternoon period (1100 to 1800 MST) that is characteristic of the results of the day's photochemical activity. Second is the photochemically- and meteorologically-quiescent night-time period (000 to 800 MST) of late night to early morning. In the summer afternoon, [PAN] increases with increasing [NO_x]. This behaviour is expected as PAN is rapidly produced by photochemistry in summer, at least in polluted air masses, and [NO_x] is a good indicator of the degree of urban pollution at this site⁹. In contrast, in the autumn and in the summer night-time the abundance of PAN is nearly constant and independent of the NO_x mixing ratio.

Figure 2 shows the mean diurnal behaviour of [PAN]. The symbols show the average PAN mixing ratio for periods when the NO_x mixing ratio was 300 p.p.t.v. or less. This [NO_x] criterion generally coincides with westerly winds at the site and is chosen as representative of relatively clean continental air masses. Figure 2 indicates that relatively constant PAN levels are encountered at this site in the summer and in the autumn in clean atmospheric conditions. The absence of a distinct diurnal cycle in the PAN levels indicates that PAN production and loss are approximately in balance throughout the day in clean continental air in the boundary layer troposphere. For these clean air masses the daily average PAN level was higher in the autumn (243 p.p.t.v.) than in the summer (170 p.p.t.v.). The PPN data gave results similar to those for PAN during both seasons at all NO_x levels with an average [PPN]/[PAN] ratio of 0.05.

For comparison, the mean diurnal behaviour of all the [PAN] data for these two seasons is also presented in Fig. 2 and is shown as the dashed lines. Here, the PAN mixing ratio does show a strong afternoon maximum in the summer but not in

Fig. 1 PAN mixing ratio as a function of the NO_x mixing ratio. For both the summer and autumn sampling periods, afternoon (1100–1800 MST) and night-time (000–800 MST) data are given. Each set of data was arranged in order of increasing $[\text{NO}_x]$. Each symbol gives the $[\text{PAN}]$ and $[\text{NO}_x]$ averages of 10 consecutive $[\text{NO}_x]$ values. The vertical bars indicate the standard deviation ($\pm 1\sigma$) of the $[\text{PAN}]$ values and the horizontal bars show the range of NO_x mixing ratios included in each average. The diagonal lines indicate equal mixing ratios for PAN and NO_x .

Fig. 2 Diurnal variation of PAN mixing ratio in the summer and in the autumn. The symbols represent averages of $[\text{PAN}]$ for a 2-h period of the diurnal cycle for the subset of the total measurements that is defined by $[\text{NO}_x] \leq 300$ p.p.t.v. The vertical bars indicate the standard deviation ($\pm 1\sigma$) of the $[\text{PAN}]$ values. The dashed lines given the corresponding averages for the full data set (all $[\text{NO}_x]$ values).

the autumn. This summer peak is attributed to both photochemistry and meteorology. During the summer, along the Front Range in the Colorado Mountains, the easterly, upslope winds increase in frequency during the daytime as a result of the daytime heating of the mountains. These easterly winds bring air containing recent (≤ 12 h) additions of pollution from the Denver metropolitan area, including high concentrations of both PAN and NO_x . The summer afternoon PAN peak observed at this site is similar in shape to that observed by Lewis *et al.*¹² in the summer in New Jersey, but with lower absolute values.

The importance of PAN relative to NO_x is shown in Fig. 3. The $[\text{PAN}]/[\text{NO}_x]$ ratio increases with decreasing $[\text{NO}_x]$ values below 500 p.p.t.v. in both summer and autumn. This increase, particularly in the autumn, is principally due to the

Fig. 3 $[\text{PAN}]/[\text{NO}_x]$ ratio as a function of $[\text{NO}_x]$ for the summer and the autumn. Each data set was arranged in order of increasing $[\text{NO}_x]$. Each symbol gives the $[\text{PAN}]/[\text{NO}_x]$ and $[\text{NO}_x]$ averages of 20 consecutive $[\text{NO}_x]$ values. The vertical bars indicate the standard deviation ($\pm 1\sigma$) of the ratio values while the horizontal bars show the range of $[\text{NO}_x]$ included in each average.

PAN levels remaining constant as $[\text{NO}_x]$ decreases. For NO_x levels < 300 p.p.t.v., the average $[\text{PAN}]/[\text{NO}_x]$ ratios are 0.5 to ≥ 1 in summer and 0.5 to ≥ 3 in autumn. The higher $[\text{PAN}]/[\text{NO}_x]$ ratio in autumn can be attributed, at least in part, to the increased stability of PAN at the lower autumn temperatures. No other determinations of the $[\text{PAN}]/[\text{NO}_x]$ ratio at comparable NO_x mixing ratios have been reported. However, there are other determinations at higher NO_x levels^{13,14} which are consistent with our results.

Figure 4 shows the observed relationship between the PAN and O_3 mixing ratios. High PAN levels are associated with high O_3 concentrations in the summer but the two are essentially decoupled in the autumn. This relationship between O_3 and PAN suggests that both PAN and O_3 are produced photochemi-

Fig. 4 Ozone mixing ratio as a function of [PAN] for the summer and the autumn. Each data set was arranged in order of increasing [PAN]. Each symbol then gives the [O₃] and [PAN] averages of 15 consecutive [PAN] values. The vertical bars indicate the standard deviation ($\pm 1\sigma$) of the [O₃] values while the horizontal bars show the range of [PAN] included in each average.

cally near the site. The photochemical production of O₃ at this site has been observed and reported earlier^{15,16}. The independence of the PAN, O₃ and NO_x concentrations in the autumn is attributed to slower photochemistry.

The precursors of PAN are peroxyacetyl (CH₃C(O)OO, or PA) radicals and NO₂. The PA radicals are produced by the reaction of acetaldehyde and hydroxyl radicals, by the photolysis of acetone and by the reactions of methylvinyl ketone and methacrolein. Each one of these compounds is itself a secondary product of hydrocarbon oxidation. Of these, acetaldehyde is likely to be the most important PA precursor. The photochemical sink of PAN is through thermal dissociation followed by reaction of PA with NO (ref. 5). During the summer day these reactions are rapid and the PAN mixing ratio tends to follow the mixing ratio of NO₂. At night, without the presence of appreciable OH and NO, the photochemical sources and sinks of PAN are interrupted, and the PAN concentration is controlled by surface deposition and atmospheric mixing. During the autumn day, the OH levels are sufficiently reduced that PAN production is effectively suppressed while the lower temperature reduces the thermal decomposition of PAN. Consequently, the PAN levels during the autumn day are relatively independent of NO_x.

It is possible to draw more quantitative conclusions from the summer data. The abundance of acetaldehyde and PA radicals that are needed to explain the observed [PAN] values can be estimated by assuming photochemical equilibrium for PA and PAN. For the summer afternoon with relatively clean air an 'apparent' acetaldehyde mixing ratio of 150–300 p.p.t.v. and PA radical concentrations of $2\text{--}3 \times 10^7$ molecules cm⁻³ are consistent with our observations. Note that the 'apparent' acetaldehyde mixing ratio deduced is an upper limit for the actual acetaldehyde mixing ratio because PA radicals can also be formed by other paths. No measurements of acetaldehyde from remote sites are available. However, in urban/suburban environments, acetaldehyde mixing ratios in the range of 0.2–20 p.p.b.v. (refs 17–19) have been reported.

From these concurrent measurements of PAN, PPN, NO_x, O₃ and meteorological parameters at a remote site in the

Colorado mountains we conclude that nitrogen oxides present in the form of PAN can be as much or more abundant than the inorganic form. The importance of PAN relative to NO_x increases with decreasing values of NO_x as well as with decreasing temperatures. It is suggested that only a modest amount of acetaldehyde and other precursors is needed to account for this PAN synthesis. The photo-oxidation of non-methane hydrocarbons probably provides these precursors in the background air. Extrapolation of these results to the upper troposphere, for which no simultaneous PAN–NO_x data are currently available, implies a highly significant role for PAN and other organic nitrates in the transport of combined nitrogen through the atmosphere. In addition, PAN can be an important source of peroxyacetyl radicals which may be important to oxidation processes in the gas as well as liquid phases.

The SRI International study is funded by NSF under grant ATM-8308816. The National Center for Atmospheric Research is sponsored by the NSF. The Aeronomy Laboratory research is supported primarily by the National Oceanic and Atmospheric Administration as part of the National Acid Precipitation Assessment Program.

Isotopic composition of atmospheric O₂ in ice linked with deglaciation and global primary productivity

M. Bender^{*†}, L. D. Labeyrie^{*}, D. Raynaud[†] & C. Lorius[†]

^{*} Centre des Faibles Radioactivites, CNRS-CEA, BP no. 1–91190, Gif/Yvette, France

[†] Laboratoire de Glaciologie et Geophysique de l'Environnement, BP 96-38402 St Martin d'Heres Cedex, France

In photosynthesis, O₂ is continuously formed from H₂O and released to the atmosphere. Coupled with respiration, photosynthesis forms a loop in which oxygen isotopes are exchanged between O₂ and H₂O. During the ice ages, sea water was enriched in $\delta^{18}\text{O}$ by $\sim 1.3\%$ relative to the present value¹. Continental waters in the areas of high primary productivity exchange rapidly with the oceans. They probably presented a similar isotopic enrichment. Since the $\delta^{18}\text{O}$ of glacial water was greater than at present, we would expect that the $\delta^{18}\text{O}$ of atmospheric O₂ was also greater than at present. Fireman and Norris² and Horibe *et al.*³ have measured the $\delta^{18}\text{O}$ of O₂ from the glacial atmosphere by analysing trapped gases in ice cores. However, their data are either too few or too imprecise to demonstrate whether $\delta^{18}\text{O}$ of atmospheric O₂

[†] Present address: Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881, USA.

has, in fact, varied. Here we present data on the changes, during the past 22 kyr approximately, in the $\delta^{18}\text{O}$ of atmospheric O_2 trapped in the ice core Dome C (East Antarctica, 74°S , 124°E). The results show that the isotopic composition of atmospheric O_2 has indeed varied along with that of sea water, and that the $\delta^{18}\text{O}$ (O_2) record offers a tool for studying several important aspects of the global cycles of O_2 and H_2O in relation to the climate.

When the snow deposited at the surface of ice sheets transforms into ice, atmospheric air is trapped in the form of bubbles. The analysis of this fossil air extracted from ice cores has already provided spectacular information, especially on the CO_2 composition of the atmosphere during the past 40 kyr (refs 4, 5). The reliability of the measurements of the composition of trapped air depends on the absence of melting during the formation and diagenesis of the solid H_2O particles, and the lack of alteration of air bubble composition during and after sampling⁶. Based on the reliable record of atmospheric CO_2 measured on the Dome C ice core⁴, we expect that it is one of the best existing cores for determining with confidence the $\delta^{18}\text{O}$ of atmospheric oxygen during the past 25 kyr. Furthermore, the special interest of this core is due to the fact that it contains a reliable high-latitude climate record, which is reflected in the $\delta^{18}\text{O}$ of the ice⁷.

To determine the $\delta^{18}\text{O}$ of O_2 , ice samples weighing $\sim 60\text{ g}$ were placed in glass flasks and evacuated to $1\text{ }\mu\text{atm}$ pressure. Trapped air was extracted from ice by melting and slowly refreezing the water, using an experimental procedure similar to the melting method described in ref. 8. The O_2 in the extracted air was converted to CO_2 by exposure for 40 min to a hot graphite rod⁹. At the end of the combustion, water was separated from CO_2 using a frozen isopropyl alcohol trap, and the water vapour pressure was measured. The $\delta^{18}\text{O}$ of the CO_2 was determined using a Micromass 602D mass spectrometer. We found that ^{18}O fractionation during combustion is geometry-dependent and not, in general, as large as values measured by Kroopnick¹⁰. The efficiencies of air extraction and O_2 conversion to CO_2 (checked by measuring the O_2/N_2 ratio in the residual gas after combustion) were estimated to be >99 and $>99.85\%$, respectively. We did not measure residual levels of CO , which may have been formed during O_2 conversion and caused our poor reproducibility for some samples. Excluded from the compilation of our data here and in Table 1 are results from 14 samples and air standards for which the water vapour pressure after combustion was $>10\text{ }\mu\text{atm}$, the carbon rod was heated to an

anomalously high temperature, or the combustion was terminated before the standard 40-min interval. Results from nine of the excluded samples are in good agreement with data presented here. The $\delta^{18}\text{O}$ of modern atmospheric O_2 , sampled in Gif and determined using the same procedure as for ice samples, is $+23.81 \pm 0.31\%$ ($n=9$ air samples) where $\delta^{18}\text{O} = 10^3 \times ([^{18}\text{O}/^{16}\text{O}]_{\text{sample}} - [^{18}\text{O}/^{16}\text{O}]_{\text{standard}}) / [^{18}\text{O}/^{16}\text{O}]_{\text{standard}}$, the standard being standard mean ocean water (SMOW)¹¹. This value of $23.81 \pm 0.31\%$ is in satisfactory agreement with the present atmospheric value of $+23.5\%$ determined by Kroopnick and Craig¹². Our measurements on three postglacial ice samples from Antarctic ice core D10 have a mean $\delta^{18}\text{O}(\text{O}_2) = 23.68 \pm 0.26\%$, and similar values were measured for postglacial Dome C samples (Table 1). These results suggest that our extraction procedure does not fractionate isotopically the oxygen initially trapped in the air bubbles of the ice and, furthermore, that this O_2 is an isotopically unfractionated sample of the contemporaneous atmosphere. Measured $\delta^{18}\text{O}$ values of past atmospheric O_2 are given in Table 1 and Fig. 1c.

Data on the $\delta^{18}\text{O}$ of the ice in ice cores, along with that of benthic foraminifera from deep-sea sediments, provide a context for interpreting the $\delta^{18}\text{O}$ of palaeoatmospheric O_2 . Normalized $\delta^{18}\text{O}$ values of benthic foraminifera in the Indian Ocean core MD73025 (ref. 13) are shown as a function of age in Fig. 1b. The 1.6% decrease in $\delta^{18}\text{O}$ between 16 and 6 kyr BP mainly reflects the addition to the ocean of glacial meltwater depleted in ^{18}O (ref. 1), although a fraction of the signal, $\sim 0.3\%$, is probably due to a warming of the deep Antarctic circumpolar waters¹⁴. The $\delta^{18}\text{O}$ decrease associated solely with continental ice melting is believed to be $1.3 \pm 0.1\%$ (ref. 14). The $\delta^{18}\text{O}$ of ice in the Dome C ice core is shown as a function of age in Fig. 1a. The sharp increase, going towards the present, reflects the marked warming at high latitudes associated with the last glacial termination. The timescale for the ice has been obtained using a simple ice flow model⁷, assuming a variable accumulation rate related to temperature changes, as suggested by comparison with well-dated events inferred from the foraminiferal $\delta^{18}\text{O}$ profile of core MD73025 (ref. 13).

$\delta^{18}\text{O}$ of O_2 gas in the Dome C core is plotted in Fig. 1c. At a given depth gases in ice are younger than ice itself because of the time required for snow to be transformed into ice and seal the bubbles⁶. According to Schwander and Stauffer¹⁵, 80% of the bubbles close off between the snow densities 0.795 and 0.830. The mean ages of the gas have been calculated assuming

Fig. 1 a, $\delta^{18}\text{O}$ of ice versus age of the ice. This plot is identical to that in ref. 7 except that the ordinate here is linear with age. b, $\delta^{18}\text{O}$ of benthic foraminifera in core MD73025 versus age. c, $\delta^{18}\text{O}$ of O_2 gas in air trapped in Dome C versus mean age of the gas. The horizontal bars correspond to the analytical uncertainty of $\pm 0.25\%$, and the arrows indicate that the mean age of the gas may be older by a few hundred years.

Table 1 $\delta^{18}\text{O}$ of O_2 in air trapped at different depths in Dome C, along with ice equivalent depth, age of the ice and estimated mean age of the gas at each level

Depth below the surface (m)	Depth in ice equivalent (m)	Age of the ice (kyr)	Mean age of the gas (kyr)	$\delta^{18}\text{O}$ of the O_2 (% vs SMOW)

that the bubbles close off at a constant rate between the densities 0.8 and 0.83. The corresponding mean age values are given in Table 1. However, different factors discussed in ref. 16 may accelerate the close off, and the mean ages of the gas may, therefore, be older by a few hundred years in the case of Dome C. This effect is suggested by the arrows in Fig. 1. Two important results emerge from the $\delta^{18}\text{O}(\text{O}_2)/\text{age}$ curve (Fig. 1c). First, during the last glacial period, the mean $\delta^{18}\text{O}$ of atmospheric O_2 was higher than the present value by 1.3%. Second, the change in the $\delta^{18}\text{O}$ of atmospheric O_2 and that of sea water (inferred from foraminiferal $\delta^{18}\text{O}$) occurred approximately simultaneously, given the uncertainties in dating procedures and scatter in the data.

Concerning the first point, the average $\delta^{18}\text{O}$ of samples younger than 7 kyr is $+23.76 \pm 0.25\%$ ($n = 5$) whereas the average $\delta^{18}\text{O}$ for samples older than 15 kyr is $+25.06 \pm 0.24\%$ ($n = 14$). Anomalous results on samples from depths of 211 and 736 m have been excluded in this averaging. Their inclusion increases the standard deviation but does not significantly change the mean values (giving $+23.90\%$ for samples younger than 7 kyr, and $+25.00\%$ for samples older than 15 kyr). Our results thus confirm the expectation discussed earlier, that the $\delta^{18}\text{O}$ of atmospheric O_2 was heavier during the last glacial than it is today. We believe that we can dismiss the possibility that this glacial/postglacial $\delta^{18}\text{O}(\text{O}_2)$ difference is due to oxygen isotope exchange in the ice. First, no inorganic reactions between H_2O and O_2 are known which occur in the absence of light at low temperatures. Second, with an ice $\delta^{18}\text{O}$ around -50% and a fractionation factor at equilibrium of $\sim 20\%$ (ref. 17), the $\delta^{18}\text{O}$ of trapped O_2 approaching isotopic equilibrium with ice would decrease progressively during ageing (to about -30%). The opposite effect is observed.

The change in the $\delta^{18}\text{O}$ of atmospheric O_2 between the last glacial and the present (1.3%) is identical to the corresponding

Fig. 2 Model values of atmospheric $\delta^{18}\text{O}(\text{O}_2)$ versus age BP, calculated for atmospheric O_2 turnover times of 1.9 and 3.1 kyr, along with $\delta^{18}\text{O}(\text{O}_2)$ values measured in the Dome C ice core. The modern atmospheric value is shown by the arrow. The calculations assume melting, at a constant rate, of 60% of all ice which melted during the last glacial termination, between 15.0 and 13.0 kyr BP, the remainder melting at a constant rate between 10.5 and 8 kyr BP. Surface sea water $\delta^{18}\text{O}$ is taken as 0‰ at present, and $+1.3\%$ before 15 kyr BP; it is assumed to vary proportionately to ice volume during intermediate times. Model calculations are done using the equation: $d\delta^{18}\text{O}(t)/dt = (\delta^{18}\text{O}(\text{ss}) - \delta^{18}\text{O}(t))/\text{TAU}$, where t is time, TAU is atmospheric O_2 turnover time, and $\delta^{18}\text{O}(\text{ss})$ and $\delta^{18}\text{O}(t)$ are the $\delta^{18}\text{O}$ values of atmospheric O_2 at steady state and at time t , respectively. The steady-state value is taken as $+23.5\%$ with respect to surface sea water.

change in sea water $\delta^{18}\text{O}$. This similarity may be surprising, as can be seen from considering the controls on the $\delta^{18}\text{O}$ of atmospheric O_2 . Isotopic exchange between water and atmospheric oxygen occurs through transfer of oxygen atoms within the biological pathways, by photosynthesis and respiration. At steady state, the $\delta^{18}\text{O}$ of O_2 consumed by respiration must be equal to the $\delta^{18}\text{O}$ of O_2 produced by photosynthesis. The $\delta^{18}\text{O}$ of photosynthetic O_2 is: $\delta^{18}\text{O}(\text{photosynthetic } \text{O}_2) = \delta^{18}\text{O}(\text{water}) + A$, where $\delta^{18}\text{O}(\text{water}) = \delta^{18}\text{O}(\text{ocean}) + W$, A equals the kinetic isotope effect during photosynthesis¹⁸ and W is the weighted mean $\delta^{18}\text{O}$ difference between the global sea water $\delta^{18}\text{O}$ and the $\delta^{18}\text{O}$ of the water which is the immediate source for photosynthetic oxygen. The $\delta^{18}\text{O}$ of respiratory O_2 is: $\delta^{18}\text{O}(\text{respiratory } \text{O}_2) = \delta^{18}\text{O}(\text{O}_2) + B$, where $\delta^{18}\text{O}(\text{O}_2)$ is the atmospheric O_2 $\delta^{18}\text{O}$ and B is the respiratory kinetic isotope effect^{19,20}. At steady state, $\delta^{18}\text{O}(\text{O}_2) - \delta^{18}\text{O}(\text{ocean}) = W + A - B$. All three terms on the right-hand side probably changed between glacial and interglacial times. W varied for terrestrial photosynthesis because of changing isotope effects in the hydrological cycle and in evapotranspiration. A and B (the kinetic photosynthetic and respiratory isotope effects) varied because different plants, animals and bacteria were responsible for O_2 production and consumption during glacial times. The similarity of the $(W + A - B)$ term between the last ice age and today, as inferred from our data, may reflect a very strong stability in oxygen isotope fractionation by the most productive marine and terrestrial ecosystems, and the hydrological regimes in which they lie.

The second interesting feature of the $\delta^{18}\text{O}(\text{O}_2)/\text{age}$ record concerns the shape of the curve during the last glacial termination. The rate at which the glacial steady-state O_2 $\delta^{18}\text{O}$ value ($+25.1\%$) approaches the postglacial value ($+23.8\%$) depends on the time course of change in the $\delta^{18}\text{O}$ of sea water due to deglaciation, and the lag in the isotopic equilibration of atmospheric O_2 with respect to photosynthesis. The latter term is, in turn, equal to the magnitude of the global O_2 reservoir divided by the gross rate of photosynthesis on the planet. The atmospheric O_2 turnover time is estimated to be in the range of 3.1–1.9 kyr (Table 2).

Table 2 Parameters for estimating the turnover time of atmospheric O₂

Global atmospheric O ₂ reservoir (GO ₂ R) = 3.7×10^{19} mol
Terrestrial net primary productivity (TNPP) = 5×10^{15} mol yr ⁻¹ (refs 21, 22)
Terrestrial gross primary productivity (TGPP) = $2 \times$ TNPP (ref. 23) = 10×10^{15} mol yr ⁻¹
Marine primary productivity (MPP) = 2×10^{15} (ref. 24)– 10×10^{15} mol yr ⁻¹ (refs 24, 25)
Global primary productivity (GPP) = (TGPP + MPP) = 12×10^{15} – 20×10^{15} mol yr ⁻¹
Atmospheric O ₂ turnover time = (GO ₂ R/GPP) = 3.1–1.9 kyr

In Fig. 2, results are given for simple model calculations of $\delta^{18}\text{O}$ (O₂) versus time (described in Fig. 2 legend), for the atmospheric O₂ turnover times estimated above. The comparison of the model curves with the observed variation in $\delta^{18}\text{O}$ of atmospheric O₂ suggests a lower limit on global productivity around the time of the last glacial termination: our data, although scattered, show that the decrease in atmospheric $\delta^{18}\text{O}$ to the postglacial values, initiated at the earliest around 13 kyr BP, was nearly complete by 9 kyr BP. The oxygen isotopic decrease was, therefore, at least as fast as estimated from the model, assuming a turnover time of 3.1 kyr (Fig. 2). This result suggests that productivity values during deglaciation were $\geq 12 \times 10^{15}$ mol yr⁻¹ (the low estimate for present productivity). This does not exclude the possibility that global primary productivity during the last glacial termination was less than at present, if current productivity is on the high side of the different estimates.

We conclude that, during the past 22 kyr, the $\delta^{18}\text{O}$ of atmospheric O₂ has changed along with that of sea water. The change reflects, in a complex way, the controls on the oxygen isotope fractionation between sea water and atmospheric O₂ and the rate of global primary productivity. In addition, since atmospheric O₂ is well mixed isotopically, $\delta^{18}\text{O}$ (O₂) is a time-stratigraphical marker. It can be used for the correlation between climatic records obtained from marine and ice cores. This is specially important for interpreting palaeo-CO₂ records from ice.

Silicon coordination changes from 4-fold to 6-fold on devitrification of silicon phosphate glass

4-Fold oxygen coordinated tetrahedral silicon (^{IV}Si) is the common building block in silicas and silicates. However, 17 crystallographically well-characterized inorganic silicates are known in which silicon exists in 6-fold oxygen octahedral coordination¹. The most notable is stishovite, a high-pressure SiO₂ polymorph^{2,3}. An interesting question is whether differences in silicon oxygen coordination between liquid and solid silicates impose a barrier to nucleation. One such case is stishovite (^{VI}Si) which cannot be synthesized from SiO₂ with ^{IV}Si at ambient pressures^{4,5}. That such an apparent nucleation barrier is not limited to silicon oxygen coordination is shown by aluminium. Thus, jadeite (NaAlSi₂O₆) with ^{VI}Al will not precipitate from its isochemical glass, in which only ^{IV}Al has been proven to exist, except when subjected to pressures > 60 kbar^{6,7}. To test if transitions of silicon coordination from 4- to 6-fold impose, in general, a barrier to nucleation, we studied the SiO₂-P₂O₅ system. X-ray diffraction studies on one of the phases in this system, SiO₂-P₂O₅, show the presence of ^{VI}Si only⁸. The aforementioned examples indicate that the silicon-phosphate glass from which this phase precipitates will also contain ^{VI}Si, as no external pressure is used. Zachariasen⁹, on the other hand, has argued against 6-fold coordination in glasses, predicting that octahedral coordination would force periodicity on the lattice, thereby disrupting the vitreous state. Our ²⁹Si MAS (magic angle spinning) NMR results show that the SiO₂-P₂O₅ glass contains only ^{IV}Si which on devitrification at ambient pressures transforms to crystalline silicon-phosphate with ^{VI}Si.

The SiO₂-P₂O₅ glasses were prepared at Corning Glass Works (Corning, New York). The glasses, which were shown to be X-ray amorphous, were devitrified at 850, 1,000 and 1,300 °C. The nature of the crystalline constituents were determined by X-ray diffraction. The X-ray pattern of the sample devitrified at 1,300 °C showed only crystals of the cubic phase of SiP₂O₇ on top of an amorphous halo. The samples devitrified at 1,000 and 850 °C contained crystals of Si₅O(PO₄)₆, SiP₂O₇ and an amorphous component¹⁰.

A single-crystal X-ray study by Tillmans *et al.*⁸ has confirmed the 6-fold coordination about Si in the cubic polymorph of SiP₂O₇ determined by earlier workers^{11,12}. They found six crystallographically distinguishable silicon sites with Si-O bonds of different lengths and a range of Si-O-P angles. All of the phosphorus exists as pyrophosphate. Si₅O(PO₄)₆ consists of isolated SiO₆ octahedra and Si₂O₇ groups with ^{IV}Si which are linked by PO₄ tetrahedra¹³. The phase diagram for this SiO₂-P₂O₅ system has been reported by Tien and Hummel¹⁴. (However, the 5SiO₂-3P₂O₅ component was incorrectly assigned^{13,15} as 2SiO₂-P₂O₅.)

²⁹Si-NMR data were collected on a Bruker CXP-300 spectrometer operating at 59.6 MHz with a MAS accessory. The magic angle was adjusted with benitoite¹⁶. The spinning rate was 2.5 kHz using an Andrew-type spinner. The chemical environments of the phosphorus atoms were also examined using ³¹P MAS NMR on a home-built 180-MHz spectrometer¹⁷ operating at 72.854 MHz.

Figure 1 shows ²⁹Si MAS NMR spectra obtained from a glass and from the same glass devitrified at the three different temperatures. The lines near -110 p.p.m. (parts per 10⁶) are characteristic of tetrahedrally coordinated Si and those around

Fig. 1 ^{29}Si MAS NMR spectra from the $\text{SiO}_2\text{-P}_2\text{O}_5$ system. The chemical shift is referenced to a quartz external standard (-107.5 p.p.m.). Excitation pulses were $4\text{ }\mu\text{s}$ long, corresponding to $\sim 60^\circ$ pulses. Delay between pulses was 20 s for the glass and 1 s for the devitrified samples. Increasing the delay up to 10 min for the glass and to 5 min for the devitrified samples did increase the intensity of the octahedral lines in the devitrified samples by $\sim 25\%$ but no octahedral signal was observed in the glass. *a*, Spectrum of the glass resulting from 12,000 FID (free induction decays). *b*, Spectrum of glass devitrified at $1,300^\circ\text{C}$. The X-ray powder pattern showed the presence of SiP_2O_7 only. The spectrum is from 72,250 FID. *c*, Glass devitrified at $1,000^\circ\text{C}$ for 6 h . The X-ray powder pattern showed the presence of both SiP_2O_7 and $\text{Si}_5\text{O}(\text{PO}_4)_6$, the latter in the greater amount. 69,700 FID. *d*, Spectrum of glass devitrified at 850°C for 16 h . The X-ray powder pattern showed that crystals of SiP_2O_7 and $\text{Si}_5\text{O}(\text{PO}_4)_6$ were present in similar amounts. 12,750 FID were co-added and transformed to give the spectrum.

-215 p.p.m. indicate the presence of the octahedral coordination¹⁸. The spectrum of the glass, shown in Fig. 1*a*, and the spectra of the three different partially crystalline samples, shown in Fig. 1*b-d*, demonstrate that silicon exhibits only 4-fold coordination in the glass but, on devitrification, 6-fold coordinated silicon appears.

The X-ray powder pattern of the sample devitrified at $1,000^\circ\text{C}$ showed twice the ratio of $\text{Si}_5\text{O}(\text{PO}_4)_6\text{:SiP}_2\text{O}_7$ that was seen in the sample devitrified at 850°C . Hence, a comparison between the spectrum in Fig. 1*b* containing only SiP_2O_7 and those in Fig. 1*c* and *d*, which contain different relative amounts of both crystalline components, allows assignment of the peaks. The SiP_2O_7 (Fig. 1*b*) shows a narrow octahedral line at -214 ± 1 p.p.m. and a broad line centred at -220 p.p.m. In Fig. 1*c* and *d*, the transition at -214 ± 1 p.p.m. changes with composition, due to $\text{Si}_5\text{O}(\text{PO}_4)_6$ having ^{29}Si . The $\text{Si}_5\text{O}(\text{PO}_4)_6$ probably also contributes to the intensity at -217 ± 1 p.p.m. These chemical shift values may be contrasted with the value of -191 p.p.m. for stishovite¹⁸ and -179.5 p.p.m. for thaumasite¹⁹, the only solids containing ^{29}Si for which ^{29}Si NMR data have been collected to date. The narrow peak in Fig. 1*c* and *d* at -120 ± 1 p.p.m. is assigned to ^{29}Si in the crystalline $\text{Si}_5\text{O}(\text{PO}_4)_6$ phase.

A substantial chemical shift of the ^{29}Si occurs relative to usual Q_1 shifts: compare ^{29}Si in $\text{Si}_5\text{O}(\text{PO}_4)_6$ with a O-Si-O angle of 180° and chemical shift of ~ -120 p.p.m. with ^{29}Si in $\text{Sc}_2\text{Si}_2\text{O}_7$ also with a O-Si-O angle of 180° and chemical shift of -93.5 p.p.m. (ref. 1). This upfield shift is attributed to phosphorus. The relative intensity of the amorphous peak that is the most downfield (-103 p.p.m.) decreases more rapidly with the progress of devitrification than does the upfield peak.

The ^{31}P -NMR spectra reflect several different environments for the phosphorus nuclei. For the glass, we see five lines with chemical shifts of 15 , -0.4 , -12 , -54 and -72 p.p.m. relative to an external standard of 85% H_3PO_4 . The partially devitrified samples showed changes in the intensity of these lines and, in the multi-component cases, a new line at -44 p.p.m. which must be due to the crystalline $\text{Si}_5\text{O}(\text{PO}_4)_6$ phase. The spectra are complicated by overlapping spinning side bands due to the large chemical shift anisotropy of ^{31}P . Assignment of the peaks is also difficult due to the range of chemical shifts which have been reported for phosphates^{20,21}.

The reconstructive transitions, requiring the making and breaking of strong Si-O bonds, which change the coordination of the Si from 4-fold in the glass to 6-fold in the crystal occurs in this system at ambient pressures. The 4 to 6-fold transition does not prohibit nucleation of the crystalline phase, indeed, the phase containing only ^{29}Si appears to nucleate first. The presence of only tetrahedral coordination in the glass is consistent with Zachariasen's prediction.

Transfer of structural information from Langmuir monolayers to three-dimensional growing crystals

Departments of Structural Chemistry* and Isotope Research†, Weizmann Institute of Science, Rehovot 76100, Israel

One enantiomer of an initially racemic mixture of α -amino acids can be preferentially removed from solution by selective incorporation into the opposite enantiotopic faces of growing centrosymmetric crystals of the α -form of glycine^{1,16}. We report here that oriented growth of crystals of the α form of glycine has been achieved under chiral Langmuir monolayers comprising amphiphilic α -amino acids, by virtue of a structural match between the monolayer and the *ac* surface layer of the attached growing glycine crystals. Such monolayers of α -amino acid of *R* configuration, containing long hydrocarbon chains, induce glycine to crystallize with its (010) face attached to the monolayer, and by symmetry the corresponding *S* amino-acid monolayers induce attachment of the (0 $\bar{1}$ 0) face of glycine. Replacement of the hydrocarbon by a fluorocarbon chain induces analogous crystallizations, albeit, with only a partial degree of orientation, whereas monolayers of a resolved amino acid bearing a cholestanoyl moiety do not promote crystallization of glycine. Monolayers of the *R*, *S*-amino acids

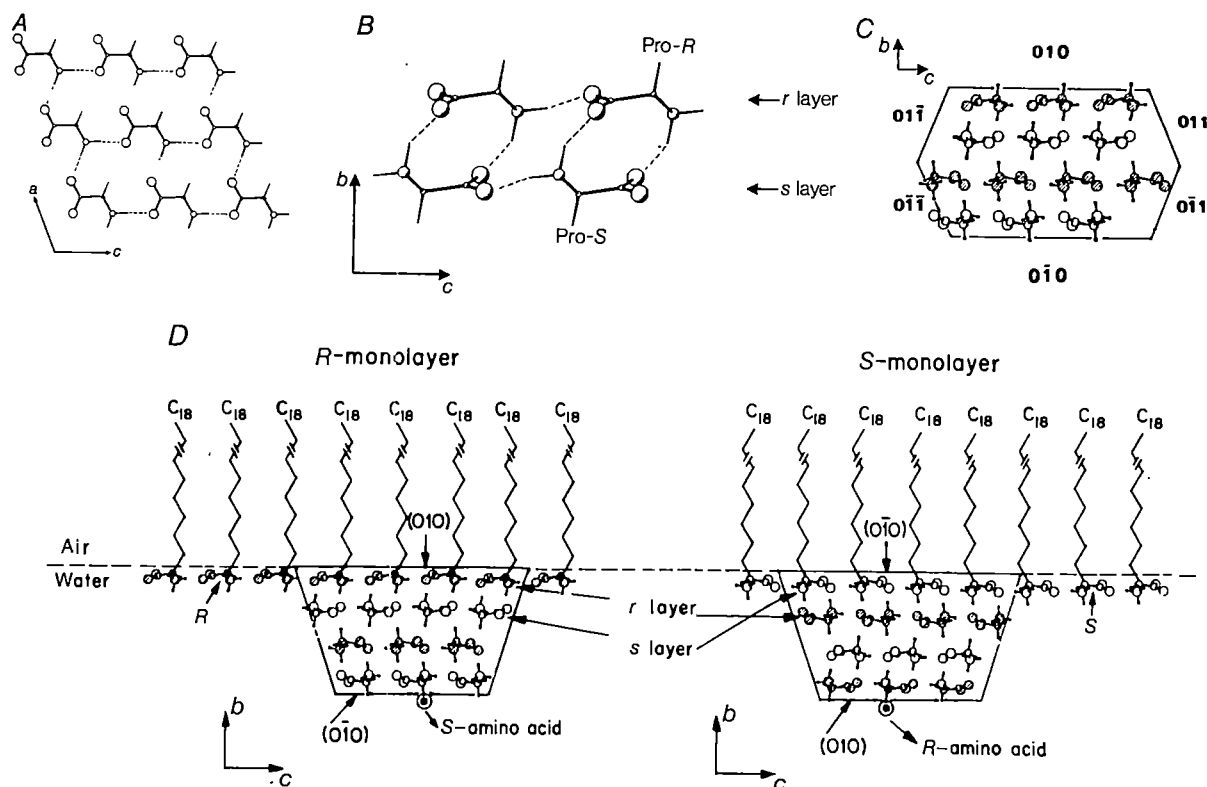

Fig. 1 A, An *ac* layer of hydrogen-bonded glycine molecules viewed along the *b*-axis. The layer is defined as *r* since the H atoms of the C—H bonds which emerge from the *ac* plane are pro-*R*. B, A centrosymmetric bilayer of hydrogen-bonded glycine molecules viewed perpendicular to the *bc* plane. The upper *r* layer is that shown in A. C, Packing arrangement of α -glycine, delineated by its crystal faces. The bilayers (B) are related by 2-fold screw symmetry along the *b*-axis. D, Schematic views of pyramidal crystals of glycine grown under compressed *R* and *S* amino-acid monolayers. The (010) face of glycine is attached to the *R* monolayer and the (0 $\bar{1}$ 0) face to the *S* monolayer. *S* and *R* amino acids are shown adsorbed from solution at the (0 $\bar{1}$ 0) and (010) faces respectively.

induce attachment of both (010) and (0 $\bar{1}$ 0) faces of glycine. These results on oriented crystal growth provide a new route for efficient amplification of optical activity of amino acids present in solution, through the enantioselective occlusion into the growing crystals of glycine¹ at water–air interfaces covered by a monolayer.

Glycine crystallizes from aqueous solution in the α -form (space group $P2_1/n$), exhibiting a bipyramidal habit¹. The glycine molecules form hydrogen-bonded chiral layers parallel to the *ac* plane² (Fig. 1A). These glycine layers (designated as *r* and *s*) are juxtaposed on one side of the *b* axis by centres of inversion about which the molecules are interlinked by N—H...O bonds into dimers to form centrosymmetric hydrogen-bonded bilayers (Fig. 1B). These bilayers are related by 2-fold screw symmetry to complete the crystal packing (Fig. 1C).

We anticipated that a densely packed Langmuir monolayer of amphiphilic homochiral α -amino acid molecules would exhibit in the aqueous subphase a hydrogen-bonded layer arrangement very similar to that in glycine, provided the hydrophobic moieties of the monolayer allow the neighbouring glycol head groups to be interlinked by N—H...O bonds. Consequently, a monolayer of, say, resolved *R*- α -amino acids packed as tightly as in an *ac* layer of glycine, should simulate an *r* layer of glycine molecules exposed at the (010) face of the crystal (see Fig. 1A, D), and thus might induce nucleation of a glycine crystal with its (010) face attached to the monolayer (Fig. 1D). By symmetry, the corresponding monolayer of *S*-amino acids should, in identical conditions, form an *s* layer and induce nucleation of a glycine crystal with its (0 $\bar{1}$ 0) face attached to the monolayer (Fig. 1D). Amphiphilic α -amino acids 1–5 (Table) were synthesized to test this hypothesis.

Condensed monolayers of compounds 1–3, measured over pure water, exhibited limiting areas per molecule in the range of 25–29 Å² (Fig. 2). These values straddle the molecular unit surface area (that is, $ac \sin \beta$) of 25.6 Å² of an *ac* layer of glycine molecules in its crystal structure. The compression isotherms of

the monolayers over aqueous solutions of glycine exhibited a distinct expanded character (Fig. 2), the effect being more pronounced with increasing concentration of glycine. This observation indicates the presence of interactions between the monolayer molecules and glycine from the subphase^{3,4}. At high compressions, all isotherms of a given compound converge (Fig. 2), indicating possible similarity in the final compressed structures of the respective films.

Monolayers 1–3 promoted immediate nucleation (within seconds after formation of the film) of pyramidal glycine crystals with their basal *ac* faces attached to the monolayer. When the *R*- α -amino acids were used, most pyramids were attached through their basal (010) faces to the monolayer and, by symmetry, when *S*- α -amino acids were used, enantiomorphous pyramids were formed with their basal (0 $\bar{1}$ 0) faces attached to the monolayer. Monolayers of racemic composition yielded attached pyramidal crystals of both types (Table 1).

With compound 5, which contains the cholestanoyl moiety, the limiting area per molecule in the monolayer is determined by the bulky steroid skeleton. It was measured to be 38 Å² (Fig. 2), a distinctly larger value than that of the glycol head group, thus precluding hydrogen bonding between the latter groups. Indeed, crystallization of glycine under such a monolayer was observed to occur at a much slower rate than with monolayers of compounds 1–3 (hours as opposed to seconds) and mostly in the bulk subphase rather than at the monolayer. In the few cases in which glycine also crystallized at the interface, these crystals exhibited both pyramidal and bipyramidal morphologies with no preferential orientation (Table 1).

For compound 4, containing a fluorocarbon chain, the situation is less clear. We might expect, with a limiting molecular surface area of the order of 30 Å² (Fig. 2)^{5,6}, that the glycol head groups would form a hydrogen-bonded layer, but with longer hydrogen-bonding distances than in the corresponding hydrocarbon monolayers. Monolayers of compound 4 of *S*

Table 1 Crystallization of α -glycine under compressed monolayers at the air-water interface

Monolayer	Limiting area per molecule (\AA^2)	Degree of orientation (%)	Face preferentially exposed to the monolayer	Rate of crystallization
1 $R\text{-CH}_3\text{-(CH}_2\text{)}_{15}\text{-CH-(NH}_3^+\text{)-CO}_2^-$ *	25	93	(010)	Fast (seconds)
$S\text{-CH}_3\text{-(CH}_2\text{)}_{15}\text{-CH-(NH}_3^+\text{)-CO}_2^-$ *	25	91	(0 $\bar{1}$ 0)	Fast
$R, S\text{-CH}_3\text{-(CH}_2\text{)}_{15}\text{-CH-(NH}_3^+\text{)-CO}_2^-$ *	25	(~50)	(010)	Fast
2 $R\text{-CH}_3\text{-(CH}_2\text{)}_{17}\text{-OCO-CH}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ †	29	>99	(010)	Fast
$S\text{-CH}_3\text{-(CH}_2\text{)}_{17}\text{-OCO-CH}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ †	29	>99	(0 $\bar{1}$ 0)	Fast
3 $R\text{-CH}_3\text{-(CH}_2\text{)}_{17}\text{-OCO-(CH}_2\text{)}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ †	29	>99	(010)	Fast
$S\text{-CH}_3\text{-(CH}_2\text{)}_{17}\text{-OCO-(CH}_2\text{)}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ †	29	>99	(0 $\bar{1}$ 0)	Fast
4 $S\text{-CF}_3\text{-(CF}_2\text{)}_9\text{-(CH}_2\text{)}_2\text{-OCO-CH}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ ‡	—‡	65-75	(0 $\bar{1}$ 0)	Fast
5 $S\text{-5-}\alpha\text{-Cholestan-3}\beta\text{-OCO-CH}_2\text{-CH-(NH}_3^+\text{)-CO}_2^-$ †	38	No orientation	—	Slow (hours)

The molecular unit surface area of α -glycine in an *ac* layer = $ac \sin \beta = 25.6 \text{ \AA}^2$. All crystallization experiments were performed at $20 \pm 2^\circ \text{C}$ by compressing the monolayers to their limiting areas per molecule over 4.66 M aqueous solutions of glycine. The monolayer area was kept constant during crystallizations. All monolayer-forming compounds have been unambiguously characterized by spectroscopic methods (NMR, MS, IR) and elemental analysis. All areas per molecule were measured over doubly distilled water at $20 \pm 2^\circ \text{C}$. The degree of orientation is defined as the percentage of crystals exposing a given attached face, that is, (010) or (0 $\bar{1}$ 0), to the monolayer. The rate of crystallization refers to the time elapsed between the compression of the film to its final area and the visual observation of first crystals attached to the film.

* Synthesized by aminolysis of α -bromostearic acid. The racemate was resolved into enantiomers by crystallization of the brucine salts of the *N*-formyl derivatives. The enantiomeric excess was determined to exceed 96% for monolayer 1(*R*) and 90% for monolayer 1(*S*) by $^1\text{H-NMR}$ and HPLC analyses of the diastereomeric *N*-formyl aminostearoyl *S*-phenylalanine methyl ester.

† Resolved compounds 2-5 were prepared by esterification of enantiomerically pure *N*-carbobenzoxy- α -benzyl aspartic or glutamic acids with the respective alcohols. The protective groups were cleaved by hydrogenolysis on Pd/C in 90% trifluoroacetic acid. The enantiomeric purity was determined to exceed 99% by gas chromatographic analyses¹³ of the respective *N*-trifluoroacetoxy diisopropyl aspartates or glutamates obtained by acidic hydrolysis of compounds 2-5 followed by derivatization.

‡ The area per molecule could not be reproduced because of technical problems (see Fig. 2).

configuration induced immediate crystallization of glycine. However, pyramids of both orientations were formed at the interface, that is, exhibiting (010) and (0 $\bar{1}$ 0) basal faces, yet with distinct preference for the latter (Table 1).

Crystallization experiments conducted with *R* monolayers of compound 2 in a range of areas per molecule showed complete orientation of glycine crystals at the monolayer up to surface areas five times its limiting value. This result suggests the formation of aggregates of very similar structure to the compressed monolayer which act as nucleation sites. The orientational effect is gradually lost at larger surface areas. Similar experiments conducted with monolayers of compounds 4 and 5 in a range of areas per molecule (up to five times their limiting areas) showed no orientational effect. These observations seem to rule out a crystallization mechanism involving a trivial surface concentration effect.

The three distinct modes of crystallization under the monolayers, fast oriented, fast unoriented and no crystallization or slow unoriented, imply a very sensitive dependence of the crystallization process on small changes in the structure of the monolayer. The fast oriented crystallization suggests the presence of a close fit between the arrangement of the glycol head groups in the monolayer and that in the *ac* layer of the glycine crystal. Departures from such a fit, possibly in only one direction, result in a significant loss of crystal orientation, without affecting the rate of crystallization. The need for cooperativity between the glycol moieties is clearly demonstrated in the third mode of crystallization, in which the nucleation rate is strongly inhibited. The observation of the fast crystallization of glycine with both (010) and (0 $\bar{1}$ 0) faces under a racemic monolayer may be interpreted not only in terms of a spontaneous enantiomeric segregation of the monolayer molecules into chiral domains⁷, similar in structure to that of the resolved enantiomers, but also in terms of other packing motifs arising from the miscibility of the *R* and *S* molecules. A detailed understanding of the structural correlation between the monolayers and the growing crystals must await atom-atom potential energy calculations and two-dimensional X-ray diffraction experiments using total external reflection of synchrotron radiation^{8,9}.

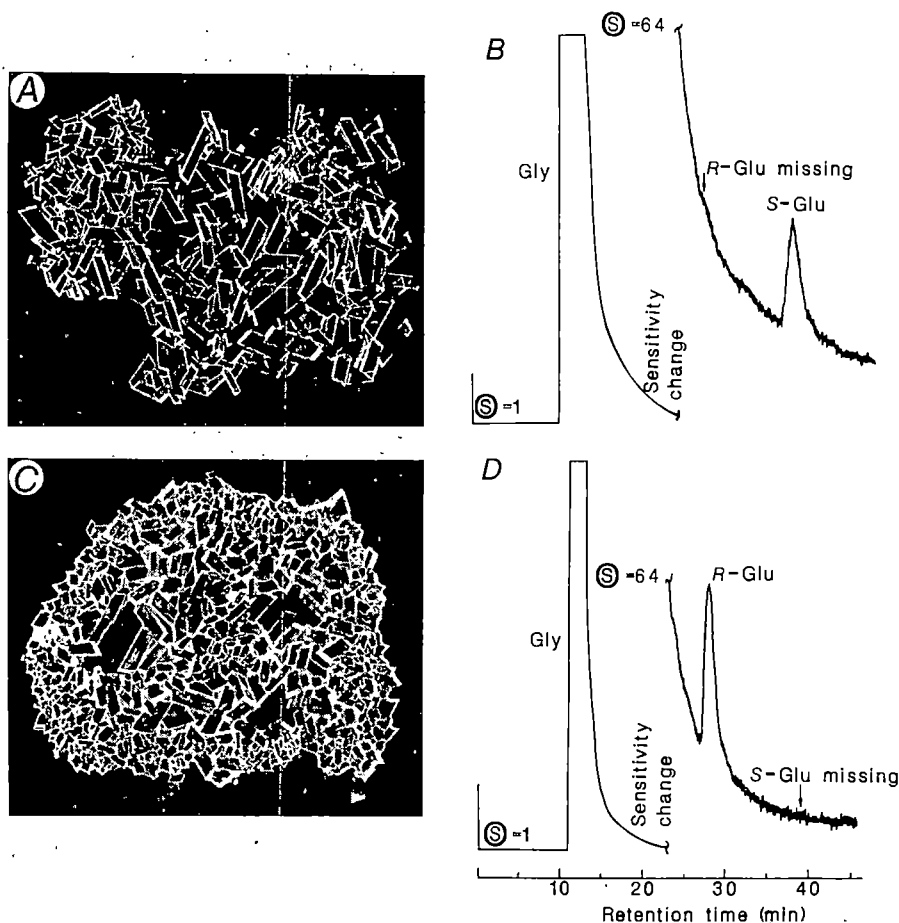

Fig. 2 Surface pressure-area isotherms measured with a thermostated circular trough equipped with a Wilhelmy balance (Mayer Feintechnik, Gottingen)¹⁴ at $20 \pm 2^\circ \text{C}$ on pure water (A) and a 2.66 M aqueous solution of glycine (B). —, Compound 2(*S*), ---, compound 5. The monolayers were spread from solutions in hexane (96%) and trifluoroacetic acid (4%). The insert displays isotherms of the fluorocarbon compound 4. The area per molecule of compound 4 could not be reproduced because of the formation of inhomogeneous spreading solutions. Expansion effects of monolayer films over salt solutions, similar to those observed here (curves B), have been reported for several systems^{3,4}.

Fig. 3 **A**, Crystals of glycine grown under a compressed monolayer of compound 2(*R*) from a 4.66 M aqueous solution of glycine containing 1% w/w *R*, *S*-Glu. All the crystals expose their (010) faces to the monolayer and exhibit the same enantiomorphous morphology. **B**, HPLC analysis of an ensemble of crystals grown as in **A** after washing with water. Conditions used: reverse-phase column (25 cm × 4.5 mm) self-packed with 5-μm Nucleosil C₁₈ (Machery Nagel). Mobile phase composition: aqueous solution of cupric acetate (4 mM) and *N,N*-dipropyl-L-Ala (8 mM) at pH 5.3–5.5 (ref. 15); post-column derivatization with *o*-phthalaldehyde and mercaptoethanol and fluorescence detection; flow rate, 0.4 cm³ min⁻¹, sensitivities \mathbb{S} as indicated¹⁵. **C**, Crystals of glycine grown under a compressed monolayer of compound 2(*S*) from a 4.66 M aqueous solution of glycine containing 1% w/w *R*, *S*-Glu. All the crystals expose their (010) faces to the monolayer and exhibit the opposite enantiomorphous morphology of those in **A**. **D**, HPLC analysis of an ensemble of crystals grown as in **C** after washing with water. Conditions as in **B**.

The ability to transfer structural information from monolayers to growing three-dimensional crystals suggests a new process for the amplification of optical activity at interfaces. It has been demonstrated previously that α -amino acids from a racemic mixture are enantioselectively occluded through the opposite {010} faces of a growing glycine crystal, leading to segregation along the *b*-axis^{1,10}. The *R*- α -amino acids are occluded only through the (010) face, whereas the *S*- α -amino acids are occluded only through the enantiotopic (0 $\bar{1}$ 0) face. Thus, when crystals of glycine were grown under an *R* monolayer of compound 2 in a solution containing racemic glutamic acid, only the *S* enantiomer was occluded into the growing glycine crystals attached to the monolayer (Fig. 3A, B), thus enriching the solution with *R*-glutamic acid. The analogous experiment performed with a monolayer of *S* configuration yielded only *R*-glutamic acid inside the glycine crystals (Fig. 3C, D), thus enriching the solution with the *S* enantiomer. The amplification effect is directly related to the number of molecular layers of the growing crystal.

The present studies are being extended to the orientational growth of other organic and inorganic crystals, also with the assistance of solid supported self-assembled^{11,12} and Langmuir-Blodgett films. This work will be reported elsewhere.

Regime and trace-element evolution of open magma chambers

Francis Albarede

Centre de Recherches Pétrographiques et Géochimiques,
Ecole Nationale Supérieure de Géologie, BP 20,
54501 Vandœuvre Cedex, France

O'Hara and co-workers^{1,2} have recently summarized some of the evidence accumulated for open-system, cyclic magmatic systems and provided useful geochemical equations for the replenishment/eruption cycles of an ideal magma reservoir. I show here that O'Hara's theory fits the situation where the volcanic eruption taps the more differentiated magma before the mixing stage. An alternative ideal model is discussed, which is applicable to the more common process of hybrid magma eruption. In mid-ocean ridge basalts, this new model may explain why large variations in incompatible elements coexist with moderate depletion of compatible elements.

Trace-element behaviour during fractional crystallization of a closed-system magma chamber is governed by the Rayleigh equation. Assuming an invariant mineralogical composition of

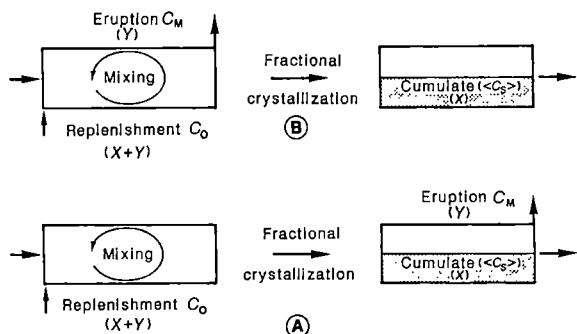

Fig. 1 The unit magmatic cycle linking replenishment, mixing, fractional crystallization and eruption for models A and B. X and Y represent the fraction crystallized and erupted in each cycle respectively. Model A is analogous to that presented by O'Hara¹ (equation (4) of the present work).

the cumulate, the concentration C_L of an element in the residual liquid is given by

$$C_L = C_{L_0} (1 - X)^{D-1} \quad (1)$$

where X refers to the mass fraction of cumulate extracted from a parent magma with concentration C_{L_0} , and D is the bulk solid/liquid partition coefficient. By mass balance, the concentration $\langle C_S \rangle$ in the bulk cumulate is given by:

$$\langle C_S \rangle = C_{L_0} \frac{1 - (1 - X)^D}{X} \quad (2)$$

O'Hara's theory describes an ideal open magma reservoir as continuously differentiating, while being periodically tapped and refilled with fresh magma which mixes homogeneously with the remaining liquid. We define C_0 as the concentration in the fresh magma, C_B as the concentration in the erupted magma, X as the fraction removed as cumulate in each cycle, whilst Y is the fraction erupted as magma during the same period. The reference is the mass of liquid which fills the chamber when replenishment resumes. At steady state, equating the elemental fluxes results in

$$X \langle C_S \rangle + Y C_B = (X + Y) C_0 \quad (3)$$

Two extreme cases will be considered that differ in their timing of eruption, replenishment and differentiation (Fig. 1):

Case A: Step 1—the reservoir is filled with a batch of fresh magma which mixes homogeneously with residual liquids from previous cycles after expulsion of some of the previous residual liquid; step 2—closed system fractional crystallization takes place within the reservoir; step 3—part of the residual liquid is expelled and the system returns to step 1.

With the present notation, $C_B = C_L$. Using equations (1) and (2), equation (3) becomes

$$\frac{C_B}{C_0} = \frac{(X + Y) (1 - X)^{D-1}}{1 - (1 - X - Y) (1 - X)^{D-1}} \quad (4)$$

which is the same equation derived previously^{1,2}.

Case B: Step 1—the reservoir is filled with a batch of fresh magma which mixes homogeneously with residual liquids from previous cycles (as in case A); step 2—part of the mixed magma is immediately erupted; step 3—closed system fractional crystallization takes place within the reservoir and the system returns to step 1.

The model differs from that derived by O'Hara in the composition C_B of the erupted magma which here equals C_{L_0} instead of C_L . Hence, equation (3) becomes

$$\frac{C_B}{C_0} = \frac{(X + Y)}{1 + Y - (1 - X)^D} \quad (5)$$

The equations for the steady-state with no crystallization ($X = 0$) are identical in both cases, whilst, as expected, they differ by a $(1 - X)^D$ term for the no-eruption limit ($Y = 0$).

Fig. 2 Functional dependence of Y and X for a couple of elements having a bulk solid/liquid partition coefficient of $D = 5$ (solid line) and $D = 0.02$ (dashed line). Numbers underlined refer to different enrichment/depletion factors, that is, different C_B/C_0 ratios (see Fig. 1 and text for symbol explanation). The hatched area along the abscissa represents conditions of crystallization which result in both moderate depletion of transition elements and large enrichment of incompatible elements.

By analogy with the concept of residence time used in the marine environment, the characteristic number of cycles required for an element to 'approach' the cyclic concentration—say to within a few per cent—may be calculated as the ratio between the amount of this element initially present in the reservoir by the increment added in each cycle. This value, which is simply $C_B/(X + Y) C_0$ can be easily calculated from equations (4) and (5).

Both cases have a simple geological interpretation. In case A, the replenishment may be first considered as a consequence of the pressure release after the eruption of the previous cycle (Fig. 1). This sort of interpretation conflicts with geological evidence from volcanoes such as Kilauea³ or Krafla⁴: eruption is commonly preceded by a period of inflation of the chamber, which is likely to be caused by inflow of magma from below. Alternatively, eruption of a liquid may be triggered by the next pulse of fresh magma. In case A, eruption of differentiated melts implies that, for some reason (such as density contrast⁵), their mixing with the new batch of fresh magma takes place very slowly; the latter magma ponds at the base of the chamber and is involved in the eruption from the next cycle only. When mixing of high-density picritic liquids is achieved before closed system crystallization, which may not be systematic according to ref. 5, their trace-element evolution will be handled appropriately by O'Hara's equation (model A). In case B, mixing and subsequent eruption of hybrid magmas take place at the onset of the magmatic differentiation. For basaltic compositions, Sparks and co-workers⁵ predict that in many cases a turbulent mixing of fresh and differentiated magmas by the rise of plumes or diapirs occurs shortly before eruption, hence supporting model B.

Each model predicts an almost identical behaviour for incompatible elements but is extremely different for elements that are preferentially incorporated in the solid. Let us consider an element with a bulk solid/liquid partition coefficient $D = 0.02$ and an element with $D = 5$. Given an enrichment (or depletion) factor C_B/C_0 of the erupted magma relative to the fresh magma,

equations (4) and (5) may be solved for Y as a function of X . This function is plotted in Fig. 2 for cases A and B, and, for each element, assuming different enrichment (depletion) factors. As pointed out by O'Hara and Mathews², O'Hara's model (case A) cannot produce melts that have large enrichment in incompatible elements and moderate depletion of compatible elements unless both the melt fractions that crystallized and erupted in each cycle are fairly small. From field and petrological evidence, O'Hara suggests values in the range of 10^{-3} – 10^{-4} for Y and, from arguments which could also be deduced from a simple examination of my Fig. 2, concludes that X is also likely to be small.

Case B is expected to produce different trace-element patterns: inasmuch as the erupted liquid contains a significant fraction of undifferentiated fresh magma, depletion of compatible elements will not be as extreme as in case A. This model predicts the existence, along the X axis of Fig. 2, of a domain which reconciles wide variations of incompatible elements and moderate depletion of compatible elements associated with sizeable fractions of accumulated solids.

This conclusion may be illustrated using the genesis of mid-ocean ridge basalts (MORB). Although the nature of the MORB parent magma is still the subject of debate, there is some agreement that MORBs are not primitive melts which have issued from the mantle^{6,7}. Several authors have suggested that mixing fresh and residual magmas in reservoirs situated under the ridge system is an efficient mechanism for buffering the MORB composition. This mechanism would lead to characteristics of a moderately differentiated magma yet explain why primitive picritic basalts are so rare^{1,8}. Other authors have presented petrographical evidence of magma mixing and crystal/melt disequilibrium^{9–11}. Bearing in mind that some of the following assumptions are controversial, let us imagine a magma chamber which emits basalts with a Ni content of 150 parts per million (p.p.m.), typical of MORB basalts, while being periodically fed by a fresh—but not necessarily primitive—magma with 300 to 450 p.p.m. of Ni. Such fresh magma resembles the most 'primitive' basalts described on the ridges as glass of phenocryst inclusions^{10,12}. According to the present models and using the same definition as above, the Ni depletion factor would lie between 0.3 and 0.5 whilst a value of 5 would seem to be a reasonable estimate of its bulk solid/liquid partition coefficient D (ref. 13). O'Hara¹ and Bryan *et al.*¹⁴ have attributed wide variations of incompatible element concentrations in MORBs, reproducing certain features of plume-type basalts, to crystallization in an open chamber periodically replenished by new parental liquid. If an increase in the concentration of an incompatible element with $D=0.02$ (Nd, for example) by a factor 10 is required, O'Hara's mechanism requires that both the erupted and the crystallized fractions be very small in each cycle (Fig. 2a), thereby implying that almost no chemical variation could be observed among samples produced at a given locality. This inferred homogeneity is a simple consequence of a nearly perfect steady state (both X and $Y \rightarrow 0$) and is clearly opposed to the variations observed in many sites over the ridge system, both on the kilometre scale¹⁵ and among melt inclusions in closely associated samples¹⁰. Deductions from the alternative model lead to different results (Fig. 2b): taking into account O'Hara's compelling evidence that Y must be small, a 10-fold enrichment of incompatible elements consistent with 10–30% of mineral fractionation and a moderate depletion of transition elements is now possible. A consequence of this model which has not yet been fully investigated is the larger number of cycles required for high- D elements to attain steady state.

I thank M. J. O'Hara and D. Velde for comments. This is CRPG contribution #619.

Elastic anisotropy may be an important factor when seismic data are used to determine the structure, composition and dynamics of the Earth's interior^{1,2}. Azimuthal anisotropy has been found in the oceanic and, although less definitely, in the continental lithosphere from field experiments where the P_n -wave velocity was observed to vary with direction^{3–5}. These studies suggest a 180° periodicity in travel-time variations as the only criterion of the presence of azimuthal anisotropy. This criterion, however, may fail to distinguish between anisotropy and lateral inhomogeneity of the isotropic medium. A new method for measuring azimuthal anisotropy has been described recently⁶, based on the phenomenon of shear-wave splitting in anisotropic media, which suggests three criteria instead of one to identify azimuthal anisotropy. We have now applied this method to the records of permanent seismograph stations in southern Germany. Our results provide strong evidence for the presence of azimuthal anisotropy in the lithosphere of the region and reveal pronounced lateral variations in the parameters of anisotropy on a scale of about 200 km.

The method⁶ was published in Russian, so we will summarize it briefly. The idea is to analyse the transverse component T of converted shear waves like SKS or SmKS. These phases have travelled part of their path as P-waves and are therefore, in a laterally homogeneous and isotropic medium, strictly polarized as SV-waves. Should they have energy on the T component, this may be due to anisotropy or/and side refraction and scattering in a laterally inhomogeneous medium. We consider a transversely isotropic medium with a horizontal axis of symmetry, which forms a particular, relatively simple variety of azimuthal anisotropy. Such a medium is often used as a model in geophysical studies of azimuthal anisotropy. The wave fields set up in this model were examined using the Thomson–Haskell matrix method extended for anisotropic media^{7,8} and the following results were obtained.

If a plane SV-wave from an isotropic half-space passes from below into a plane horizontal, homogeneous, transversely isotropic layer with a horizontal axis of symmetry, then the incoming wave splits into two quasi-shear waves. Under realistic assumptions of the properties of the Earth's mantle (magnitude of anisotropy is of the order of several per cent, anisotropic layer thickness is of the order of 100 km, and the angle of incidence of the SV-wave is of the order of 10°), the time delay δt between the two quasi-shear waves at the top of the layer is of the order of a fraction of a second. For periods around 10 s, we may assume that $\omega \cdot \delta t \ll 1$, where ω is the circular frequency. Then, at the top of the layer, the quasi-shear waves interfere either constructively (in the radial component R) or destructively (in the transverse component T). The properties of the R

Fig. 1 Location map of the seismograph stations used and the major tectonic units of the area in southern Germany. The vertical components of the Gräfenberg array are marked by triangles, horizontal components by circles. A three-component station is located at Stuttgart. The arrows mark the directions of the fast velocity of the anisotropy observations. They are 50° at Stuttgart (a) and 0° at the Gräfenberg array (b). An averaged direction of 20° (c) results from a study of many P_n -arrival times over the entire area of southern Germany⁵. Our study indicates that the general anisotropy of the area appears to break up into smaller units if a method with higher spatial resolution is used.

component are weakly dependent on the azimuth of propagation of the incoming wave, while major variations occur in the T component.

If the angle between the azimuth of the wave propagation and the axis of symmetry is 0, $\pi/2$, π or $3\pi/2$, the T component is equal to zero. If the angle is $\pi/4$ or $5\pi/4$ and the R component of the incoming wave is represented as $2 \cos(\omega t)$, then R and T at the top of the layer can be expressed in first approximation by

$$R(t) \approx \cos(\omega t) + \cos(\omega t + \omega \delta t) \approx 2 \cos(\omega t)$$

$$T(t) \approx \cos(\omega t) - \cos(\omega t + \omega \delta t) \approx (\omega \delta t) \sin(\omega t)$$

These equations mean that the harmonic T component is shifted in time with respect to the R component by a quarter of a period, while the amplitude of the T component is proportional to frequency. The equations are also valid for the angles $3\pi/4$ and $7\pi/4$, but the expression for T changes sign. This change implies that the azimuthal variations of T are periodic with the period of π . The conclusions thus derived are in general corroborated by the calculation for other angles, while some minor complications resulting from sparse and noisy observational data may be neglected.

In summary, the long-period, harmonic T component of the displacement set up in the model considered is characterized in first approximation by the following properties⁶: (1) It is periodic as a function of the azimuth of the wave propagation; the dominant period is 180°. (2) It is shifted in time with respect to the radial component R by a quarter-period. (3) The T/R amplitude ratio is inversely proportional to the period.

Fig. 2 Plots of $F(t, k, \psi)$ for the records of STU (modified from ref. 6). The largest deviations of $F(t)$ from 0 are observed in the right column ($k=2$) on the two top traces (marked by an arrow). These traces can be well approximated by the function $-0.12 \sin(2\pi t/10)$.

Thus, this approach suggests three independent diagnostic properties of azimuthal anisotropy instead of one in the conventional method. If all of them are observed, the probability is high that the observed effects are due to azimuthal anisotropy.

In order to extract the diagnostic properties of azimuthal anisotropy from seismic data, many earthquake recordings of the same seismograph station must be processed jointly. The combined processing of records of events with different magnitudes and different source signals requires standardization of the records. The normalized transverse component $\hat{T}(t)$ is computed for that purpose:

$$\hat{T}(t) = \int_{t_1}^{t_2} T(t+\tau) R(\tau) d\tau / \int_{t_1}^{t_2} (R(\tau))^2 d\tau$$

where the times t_1 and t_2 correspond to the beginning and end of the converted wave train and τ is the variable of integration. The use of $\hat{T}(t)$ instead of the transverse component $T(t)$ itself makes all the earthquakes directly comparable.

As an additional tool for the analysis of the azimuthal dependence, a harmonic analysis is performed

$$F(t, k, \psi) = \sum_i \hat{T}_i(t) \cos(k\varphi_i + \psi) / \sum_i (\cos(k\varphi_i + \psi))^2$$

where \hat{T}_i corresponds to the i th seismic event, φ_i is the back azimuth of the epicentre of the i th event, k is the harmonic number and ψ varies in the range from 0 to 180°. The phase ψ_0 of the k th harmonic is given by the value of ψ , which corresponds to the maximum value of $|F(t, k, \psi)|$. Denoting by t_0 the value of t which corresponds to this maximum, we may define the amplitude of the k th harmonic as $|F(t_0, k, \psi_0)|$. Obviously the values of t_0 and ψ_0 are different for different harmonics. The minimum values of $|F(t, k, \psi)|$ correspond to $\psi = \psi_0 \pm \pi/2$ and can be used to locate ψ_0 .

$F(t, k, \psi)$ can now be examined for the three properties related to azimuthal anisotropy. The 180° periodicity of the T component is observed if $|F(t_0, 2, \psi_0)|$ is greater than $|F(t_0, 1, \psi_0)|$. The property of the phase shift between $R(t)$ and $T(t)$ is observed if the shape of $F(t, 2, \psi_0)$ is close to the sine function

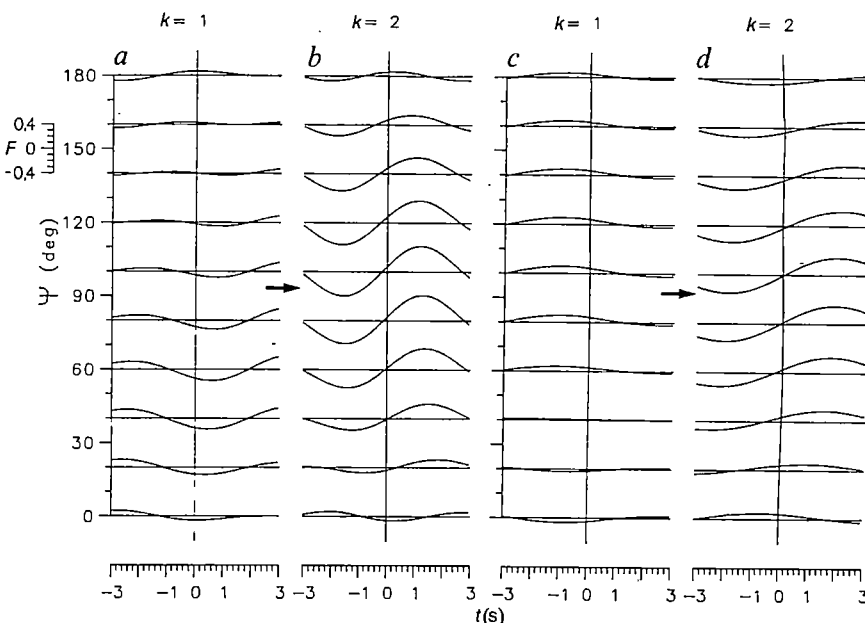

Fig. 3 SKS records of events 2, 15 and 8 of Table 1. The *R* and *T* components of these events are shown after passing through a shorter (left) and a longer (right) period bandpass filter. The numbers on the traces indicate back azimuths of the events in degrees. The letters *A* and *C* are the symbols for different sub-arrays. Note the phase shifts between the components (dotted lines).

Fig. 4 Plots of $F(t, k, \psi)$ for the records of GRF. A 4–8-s bandpass is used for *a* and *b*; and a 8–15-s bandpass for *c* and *d*. The largest deviations of $F(t)$ from 0 occur on the traces corresponding to $k=2$ and the values of ψ around 90° (marked by arrows). These traces can be well approximated by $0.4 \sin(2\pi t/6)$ (see *b*) and $0.3 \sin(2\pi t/8)$ (see *d*). The smallest values of $|F(t, 2, \psi)|$ correspond to the values of ψ around 0 and 180° conforming to $\psi_0 = 90^\circ$. Note the differences between the values of $F(t, 2, \psi)$ at GRF and STU (Fig. 2). They indicate pronounced differences in the parameters of azimuthal anisotropy.

$\sin(\omega t)$ or $-\sin(\omega t)$. The third property is observed if the values of $F(t_0, 2, \psi_0)$ are inversely proportional to the period. This requires, of course, that records in different frequency bands are available.

The direction of the fast velocity α (measured clockwise from north) can be found from the expression

$$\alpha = -\psi_0/2 + 3\pi/4$$

This expression was given in ref. 6 on the assumption that the shape of $F(t, 2, \psi_0)$ is close to $-\sin(\omega t)$. It may happen, however, that it is close to $\sin(\omega t)$. Then, instead of ψ_0 , one should use $\psi_0 + 180^\circ$.

The records of SKS and SKKS from the seismograph station STU (Stuttgart, Fig. 1) were available in the form of particle-motion plots for events of the years 1949–55 (ref. 9). It was impossible to filter these data, and the dominant periods were close to 10 s. The resulting plots of $F(t, k, \psi)$ (see Fig. 2) show that, for $k=2$, ψ_0 is close to 160 – 180° , $|F(t_0, 2, \psi_0)|$ is close to 0.12 and the diagnostic properties of azimuthal anisotropy are clearly observed: (1) The amplitude of the second harmonic $|F(t, 2, \psi_0)|$ is larger than $|F(t, 1, \psi_0)|$, implying that the influence of anisotropy is stronger than that of lateral inhomogeneity. (2) The shape of $F(t, 2, \psi_0)$ is close to the sine function, indicating the proper phase shift between the *R* and *T* components. The direction α is close to 50° . On the assumption of 7% anisotropy, the thickness of the anisotropic layer was estimated as 50 km (ref. 6).

The method was further applied to the digital broadband records of GRF (Gräfenberg array, Fig. 1; a description of this installation is given in ref. 10). The first step in processing the

records was to form beams of the radial and transverse components of the three-component stations of the array. The analysis was carried out in two frequency bands, one between 4 and 8 s and the other between 8 and 15 s. A list of the events used is given in Table 1.

Figure 3, showing examples of the filtered seismograms, indicates that considerable energy is present in the *T* component, which can only be caused by anisotropy or lateral inhomogeneity. Also clearly observable is the phase shift between the components, which can only be due to anisotropy. The properties of the plots of $F(t, k, \psi)$ (see Fig. 4) are in perfect agreement with those theoretically predicted for azimuthal anisotropy, namely: (1) the second harmonic ($k=2$) is much stronger than the first one; (2) the shape of the curve $F(t, 2, \psi_0)$ (ψ_0 is nearly 90°) is close to $\sin(\omega t)$; (3) the amplitudes of the second harmonic (0.4 for the shorter periods and 0.3 for the longer periods) are inversely proportional to the periods.

The observations at GRF provide decisive evidence for azimuthal anisotropy. The parameters of anisotropy, however, are different from those found at STU. The value of α at GRF can be estimated as 0° and the magnitude of the effect of anisotropy is twice as large as that found at STU. The difference between the values of α at GRF and STU is 50° , which is larger than the possible errors of measurement by an order of magnitude. This difference implies that the observed anisotropy is characteristic of the lithosphere and, perhaps, the top of the asthenosphere, since lateral variations of anisotropy on a scale of about 100 km in the deeper parts of the mantle would be averaged out by the summation procedure. We note that our estimates of α are close to those found from the teleseismic

Two phases were used for some events. Phases travelling in opposite directions across the globe have also been used in two cases.

P-wave travel-time residuals¹¹. The study of P_n -velocities on profiles crossing the same area in many directions has revealed a high velocity at the top of the mantle in an azimuth of 20° (ref. 5). This direction appears as the average of the substantially different directions at GRF and STU. The change of the direction of the high velocity between GRF and STU conforms to the shape of the strip of the outcrops of Jurassic rocks (Fig. 1). This conformity is either a coincidence or, more likely, the result of a relationship between the deep and shallow structure in the lithosphere.

The pronounced variations in the parameters of anisotropy within a small area imply that continental anisotropy is a relatively small-scale phenomenon compared with oceanic anisotropy. This difference is not surprising in view of the long and complicated history of the continental lithosphere. The term 'laterally inhomogeneous anisotropy' gives a proper description of the situation.

Finally, we note that the method⁶ has several advantages over conventional P_n -techniques. It does not require expensive field experiments and, as shown here, can provide higher lateral resolution. Moreover, it takes full advantage of the phenomenon of shear-wave splitting, which may be regarded as the most convincing evidence for the presence of anisotropy. Taking this into account, we recommend the method⁶ for widespread mapping of azimuthal anisotropy in the continental lithosphere. Data from dense, perhaps portable, broad-band seismograph networks would be ideally suited for this purpose.

This research was supported by the Deutsche Forschungsgemeinschaft. We thank M. Wyss and M. Hellweg for reading the manuscript.

Near-synchronicity of New Zealand alpine glaciations and Northern Hemisphere continental glaciations during the past 750 kyr

C. S. Nelson, C. H. Hendy, G. R. Jarrett
& A. M. Cuthbertson

School of Science, University of Waikato, Hamilton, New Zealand

The Brunhes magnetochron (0–730 kyr) at Deep Sea Drilling Project Site 594 off eastern South Island, New Zealand, comprises up to ~100 m of alternating units of pelagic and hemipelagic ooze formed during interglacial and glacial periods respectively. The youngest hemipelagic interval corresponds to glacial isotope stage 2 and can be correlated with extensive glacial and glacio-fluvial deposits of the late Last Glaciation (~27–13 kyr BP) on South Island. Inferring the same genetic link for the other hemipelagic sediment units down core, we show here that as many as 12 major episodes of expanded alpine glaciation have occurred on South Island in the past 730 kyr. Each of these glacial episodes coincided with a period of significant ¹⁸O enrichment (+2‰) in the core resulting from changes in ocean isotope composition associated with major growth phases of the Northern Hemisphere ice sheets. The inferred history of alpine glaciations on this remote South Pacific island appears to be closely phase-locked (±3 kyr) to world-wide climate changes.

Site 594 of the Deep Sea Drilling Project Leg 90 is located on the southwestern margin of the Chatham Rise, 300 km east of New Zealand's South Island, in a water depth of 1,204 m (Fig. 1). The site lies in the sub-antarctic water mass immediately south of the Subtropical Convergence. The upper 170 m of the section was drilled with 95% recovery using an hydraulic piston corer¹ and provided largely undisturbed cores comprising conspicuously alternating units of light-coloured pelagic and dark-coloured hemipelagic oozes of Pliocene–Quaternary age^{2,3}. Seismic profiles⁴ demonstrate that this sedimentary sequence is

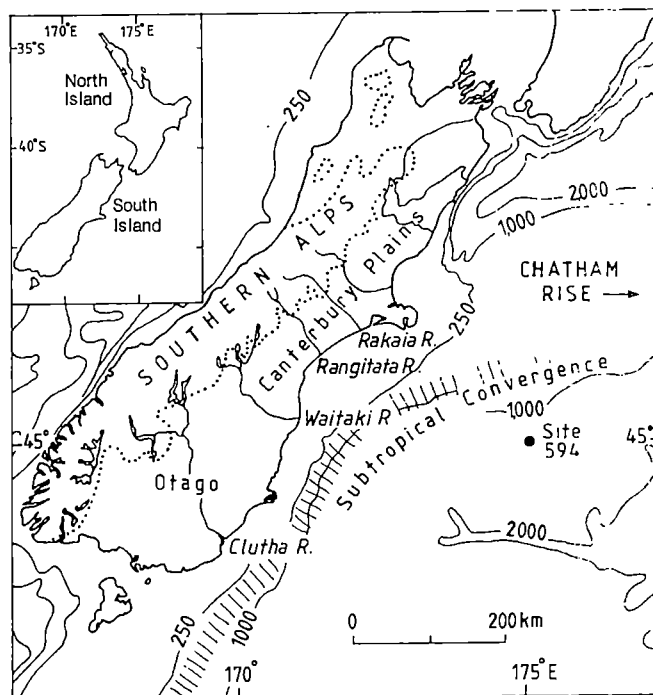

Fig. 1 Location map for DSDP Site 594 (45°31.41'S, 174°56.88'E) off South Island, New Zealand, showing also the approximate position of the oceanic Subtropical Convergence and some relevant physiographical features on South Island. The dotted line on land shows the probable extent of glacial ice at about 18 kyr BP (ref. 16).

Fig. 2 Colour (a), texture (b), calcium carbonate (c), quartz (d), plagioclase feldspar (e) and planktonic and benthic foraminiferal oxygen-isotope (f and g respectively) records for the late Quaternary section of Site 594 to the Brunhes-Matuyama (B/M) boundary (730 kyr), tentatively placed at about 99.4 m sub-bottom depth³, although other options are possible. White- and black-coloured intervals (a) are dominated by pelagic and hemipelagic oozes respectively; crossed intervals represent missing core. The mean age resolution of sample points in most plots is ~2.4 kyr. In the cumulative percent textural plot (b): S, sand (>0.06 mm); C, clay (<0.004 mm); Z, silt (0.004–0.06 mm); T, tephra layer. Numbers 1–26 in the carbonate record (c) refer to major intervals of high (odd numbers) and low (even numbers) calcium carbonate content. Note that compared with the light-coloured pelagic ooze intervals the dark-coloured hemipelagic sediment units are characterized by depletion in sand and clay sizes, low carbonate contents, relatively increased amounts of quartz and feldspar, and significant ^{18}O enrichment, properties consistent with their formation during full glacial episodes. Analytical procedures and data are recorded in refs 5, 6.

regionally extensive off eastern central South Island. Here we discuss only the late Quaternary interval of core, which is complete and exceptionally thick, the Brunhes normal magnetochron (0–730 kyr) possibly extending to about 99.4 m sub-bottom depth³.

The pelagic sediments are mainly impure foraminifer-bearing nanofossil oozes whose relative enrichment in both sand- and clay-sized material (Table 1) reflects their increased proportions of foraminiferal tests and coccolith plates respectively. The hemipelagic sediment units are more variable in composition, but are typically nanofossil-, diatom- and/or sponge spicule-bearing terrigenous clayey silts with a preponderance of silt-sized quartz, sodic plagioclase, chlorite and mica minerals (Table 1).

The bulk sediment texture, calcium carbonate content and relative abundance (from X-ray diffraction) of quartz and feldspar have been determined for 315 samples collected at 30 cm intervals through the section^{5,6}, equivalent to a mean age resolution of one sample per 2.4 kyr over the past 750 kyr. These sedimentary parameters exhibit strong in-phase cyclical fluctuations down core (Fig. 2a–e). Using the carbonate stratigraphy as a basis, 26 major sedimentary alternations occur in the top 100 m of core (Fig. 2c), 13 of predominantly pelagic character (odd numbers 1 to 25) and 13 with mainly hemipelagic properties (even numbers 2 to 26).

Oxygen-isotope measurements were made on both planktonic (*Globigerina bulloides*) and benthic (mainly *Uvigerina* sp.) foraminifera from the same samples used for the sedimentary analyses⁵ (Fig. 2f, g). Despite superimposed high-frequency

fluctuations, the isotope curves display overall in-phase cyclical variations of about 2‰ in ^{18}O enrichment and depletion which in turn match the sedimentary fluctuations corresponding to the hemipelagic and pelagic ooze units respectively. Such extreme variations in the isotope composition of the ocean, as recorded in the foraminiferal tests, are controlled primarily by changes in global ice volume^{7,8} and clearly associate the hemipelagic sediments with glacial conditions and the pelagic ones with interglacial periods.

This strong interrelationship between climate and sedimentation suggests that the abundant terrigenous material in the hemipelagic deposits resulted primarily from greatly increased rates of erosion on the South Island during glacial periods and the rapid transferral of this terrigenous detritus to off-shore areas where sedimentation rates increased and the carbonate content of bottom sediments was diluted (Table 1). Direct evidence for greatly increased rates of erosion and supply of sediment from South Island comes only from the nature and distribution of on-land^{9,10} and off-shore^{11,12} deposits associated with the last major glacial advances in New Zealand, between ~27 and 13 kyr BP (ref. 13). This timing matches closely isotope stage 2 (ref. 8), which is clearly represented by the hemipelagic deposit between ~1.5 and 5.5 m sub-bottom depth in our core (unit 2 in Fig. 2c), and is discernible also in other cores from the region¹¹. At this time the lowlands of South Island east of the Southern Alps accumulated thick deposits of greywacke and schistose gravels and sands^{14–16}, commonly in the form of extensive coalescing outwash fans, such as Canterbury Plains (Fig. 1). The major eastward-draining South Island rivers also

Table 1 General sediment properties of the pelagic and hemipelagic oozes in the late Quaternary section at DSDP Site 594

Property	Pelagic oozes	Hemipelagic oozes
Colour	Light blueish-grey	Dark greenish-grey
Bulk sediment grain size		
% Sand (>63 μm)	10–30	0–10
% Silt (4–63 μm)	50–70	70–90
% Clay (<4 μm)	25–30	10–25
Calcium carbonate (%)	40–80	0–25
Nannofossils (%)	Abundant (40–75)	Rare to common (1–25)
Foraminifers (%)	Common (5–25)	Rare (1–5)
Siliceous microfossils (%) [*]	Absent to rare (0–10)	Rare to common (5–30)
Terrigenous minerals (%) [†]	Rare to common (10–40)	Abundant (30–75)
Sedimentation rates (cm kyr^{-1}) ⁵	5–10	10–35

^{*}Includes sponge spicules, diatoms, radiolarians and silicoflagellates.

[†]Includes quartz, plagioclase, chlorite and micas.

generate high proportions of suspended load^{17,18}. For example, 94% of the quartzofeldspathic chlorite schist supplied originally as bedload to the Clutha River (Fig. 1), a major source of the marine sediment off Otago and south Canterbury^{12,19}, is abraded to silt and finer sizes during its course to the sea¹⁷. During glacial periods the reduced shelf width accompanying lowered sea levels undoubtedly enhanced deep-water mud deposition^{11,12}. Moreover, the occurrence of widespread deposits of loess of Last Glacial age in east Canterbury and Otago²⁰, and the significant increase in the content of aeolian quartz in 18–15-kyr-old deep-water sediments east of New Zealand compared with their modern counterparts^{21,22} suggest that a significant proportion of the terrigenous silt in the hemipelagic sediments at Site 594 may be of aeolian origin, picked up from the extensive outwash surfaces on eastern South Island and transported offshore by the prevailing westerly wind system, which was intensified during glacial times¹³.

Thus hemipelagic unit 2 at Site 594 is the off-shore sedimentary result of climatic deterioration associated with the latest phase of extended alpine glaciation in South Island, and is directly correlatable with isotope stage 2 reflecting the last period of major expansion of the Northern Hemisphere ice sheets. The similar nature of the hemipelagic sediment intervals throughout the section (Fig. 2) strongly suggests that every hemipelagic unit reflects a major period of increased erosion and outwash aggradation associated with expanded glaciation in South Island. Moreover, because each hemipelagic interval corresponds to a period of significant (+2%) ¹⁸O enrichment (Fig. 2f, g) reflecting mainly changes in the isotope composition of the ocean due to an increase in the volume of global ice, then each episode of alpine glaciation coincided with a world-wide period of glacio-eustatically lowered sea level. The late Quaternary marine oxygen-isotope changes have been controlled primarily by the growth and retreat of continental ice sheets in the Northern Hemisphere^{7,23}; an accord between the marine ¹⁸O record and the northern European glacial record inferred from loess sequences has been demonstrated by Kukla²⁴.

That every major ice growth phase indicated by our oxygen-isotope data (Fig. 2f, g) can be closely matched through the hemipelagic units to a period of expanded alpine glaciation on a small temperate-latitude island in the Southern Hemisphere is evidence that the latter does not reflect simply local or isolated climatic events, but rather world-wide climate change. Moreover, since no consistently discernible phase difference is evident between the isotope and lithological records (Fig. 2), the climatic and sedimentary response in New Zealand to fluctuations in the world's continental ice sheets has been rapid, within the 2–3-kyr period represented by our sample spacing.

Finally, it is unfortunate that some uncertainty surrounds the exact position of the Brunhes–Matuyama boundary in this high-

resolution record²⁵, the location chosen here (Fig. 2a) being that adopted in Leg 90 of the *Initial Reports of the Deep Sea Drilling Project*^{3,5,25,26}. If this placement is correct, and the Brunhes sedimentary record at Site 594 is genuinely free of unconformities, then there have been 12 full glacial periods and 13 major interglacial episodes over the past 730 kyr (Fig. 2c), more than is implied by the standard 19 oxygen-isotope stage scheme for this time interval⁸. However, it might be argued from the shape and amplitudes of the isotope and carbonate records in Fig. 2 that the Brunhes–Matuyama boundary lies nearer 84 m sub-bottom (W. F. Ruddiman, personal communication, 1985), and that the first 19 sedimentary units defined here (Fig. 2c) match the recognized number of isotope stages for the Brunhes magnetochron. This important chronological aspect of the late Quaternary climate record at Site 594 remains to be resolved and is under investigation.

We thank Professor Michael Selby (University of Waikato) and Dr William Ruddiman (Lamont Observatory) for helpful comments, the New Zealand University Grants Committee for financial assistance (grant 88/125) of the project, and the Deep Sea Drilling Project for logistic support.

First Mesozoic mammal from Australia—an early Cretaceous monotreme

Michael Archer*, Timothy F. Flannery†, Alex Ritchie† & R. E. Molnar‡

* School of Zoology, University of New South Wales, PO Box 1, Kensington, New South Wales, Australia 2033

† Australian Museum, 6–8 College Street, Sydney, New South Wales, Australia 2000

‡ Queensland Museum, Fortitude Valley, Queensland, Australia 4006

Here we describe Australia's first known Mesozoic mammal and the first known early Cretaceous mammal from Gondwanaland. *Steropodon galmani* n. gen. and sp., discovered in early Cretaceous sediments at Lightning Ridge, New South Wales, Australia, appears to represent an ornithorhynchid-like monotreme. This

discovery represents the first record of a fossil mammal from Australia that is older than 22.4 ± 0.05 Myr^{1,2} and the specimen is, by more than 85 Myr, the oldest known monotreme. As the oldest monotreme, it will necessitate a radical revision of present understanding about dental homology in the middle Miocene *Obdurodon insignis*, the only fossil monotreme previously known to have had teeth³. The structure of *S. galmani* supports one current view⁴ that monotremes, one of three groups of living mammals (the other two being marsupials and placentals), are phylogenetically close to the other groups of living mammals.

The opal-bearing sediments at Lightning Ridge consist of a suite of siltstones and poorly sorted sandstones referred to the early Cretaceous Griman Creek Formation⁵. In New South Wales this formation includes the Wallangulla Sandstone Member⁶, the unit from which the new monotreme was obtained. The Griman Creek Formation is dated as middle Albian, based on palynological evidence⁹. This age is supported by the discovery in the formation of hypsilophodontid dinosaurs that are very similar to those found in the Strzelecki Group of Victoria, which has been fission-track-dated as Aptian-Albian⁷. At Lightning Ridge the Griman Creek Formation was apparently deposited in the shallow estuary of a westward-flowing river. Some of the formation's invertebrate fossils are clearly marine but others, including viviparid snails, indicate a freshwater influence. Cross-bedding is present, as are apparent impressions of plant roots^{5,8}. Many of the tetrapod bones indicate transport. In addition to *S. galmani*, the vertebrate fauna from Lightning Ridge consists of teleosts, ceratodontid lungfish (*Ceratodus wollastoni* and *Neoceratodus forsteri*), turtles, plesiosaurs, crocodilians ('*Crocodylus*' *selaslophensis*), and theropod (*Rapator ornitholestoides*), ornithomimid (*Fulgurotherium australe*) and sauropod dinosaurs^{6,10,11}. There is no evidence that any of the fossils represent an intrusion of later material into the Griman Creek Formation.

The dental terminology¹² used here for *S. galmani* assumes that the teeth are tribosphenic and the cusps are homologues of topographically analogous cusps in therian mammals.

Class Mammalia

Subclass Monotremata

Family ?Ornithorhynchidae

Genus and species: *Steropodon galmani* n. gen. and sp. (Figs 1, 2).

Etymology: *Sterope* is Greek for 'flash of lightning' and *odon* is Greek for 'tooth', the name being an allusion to Lightning Ridge, the type locality, as well as to the opalescent nature of the fossil teeth.

Holotype: Australian Museum Palaeontology collection no. AM F66763, a right dentary fragment with M₁₋₃ in place, obtained from an opal miner by David and Alan Galman in 1982 or 1983. This specimen is, like all fossils from this locality, a natural opal pseudomorph of the original. Accordingly, there is no preservation of the internal bone or tooth structure although cavities in the original, such as alveoli and the mandibular canal, have been differentially preserved. The teeth preserved in the holotype have been interpreted as M₁₋₃ because the alveolus anterior to the anteriormost molar is very small. This indicates that there was an abrupt change in shape between M₁ and the tooth presumed to be a premolar situated anterior to it.

Locality: Lightning Ridge, New South Wales, Australia.

Stratigraphy: Wallangulla Sandstone Member of the Griman Creek Formation.

Age: Albian⁹.

Diagnosis: This taxon differs from all other monotremes (species of *Obdurodon*, *Ornithorhynchus*, *Tachyglossus* and *Zaglossus*) in its retention of a cristid obliqua and talonid basin and in its possession of a pre-entocristid. It differs from non-monotrematous mammals in its combination of the following features: three lower molars, an antero-posteriorly very compressed trigonid, a transverse metacristid, a well-developed and wide talonid, a pre-entocristid/cristid obliqua/distal metacristid conjunction, absence of a paraconid on M₁, absence of

Fig. 1 The holotype of *Steropodon galmani* n. gen. and sp. in occlusal view (a), buccal view (b) and lingual view (c).

hypoconulids, presence of a distinctive distal metacristid and molars that exhibit essentially transverse shearing crests.

Description: While a more detailed description is in preparation, the above diagnosis, the comments made below and the illustrations (Figs 1, 2) will suffice for present purposes.

A posterior, elongate, shallow horizontal depression on the lingual side of the dentary extends from the posterior broken edge of the dentary forward to the level of the posterior root of M₃; this may represent a groove for the meckelian cartilage or it may be the result of pre-depositional breakage that seems to have affected other areas of the posterior part of the jaw fragment.

We conclude that *S. galmani* is a monotreme for the following reasons. Its antero-posteriorly very compressed trigonid,

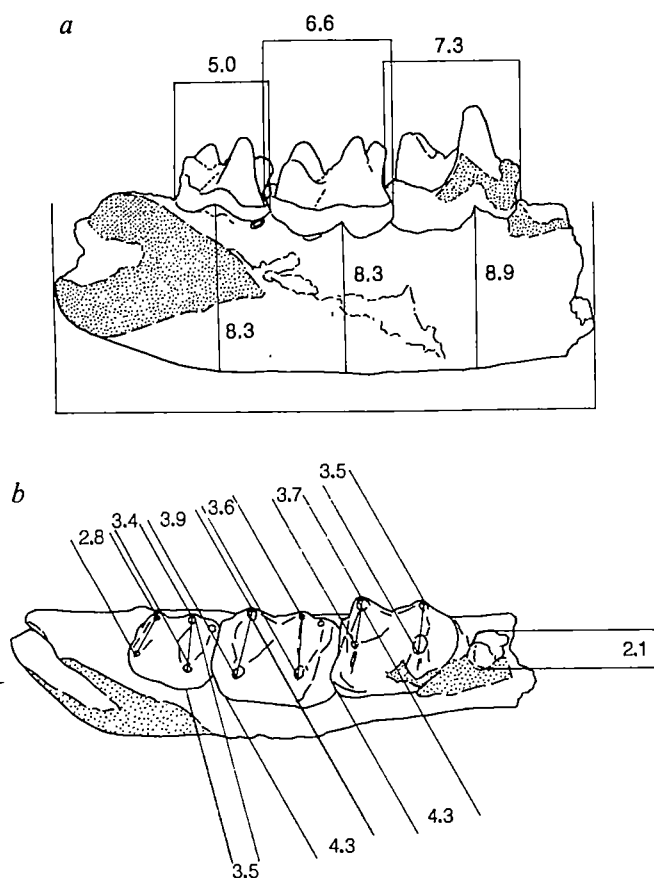

Fig. 2 Measurements (in mm) of the holotype in buccal view (a) and occlusal view (b).

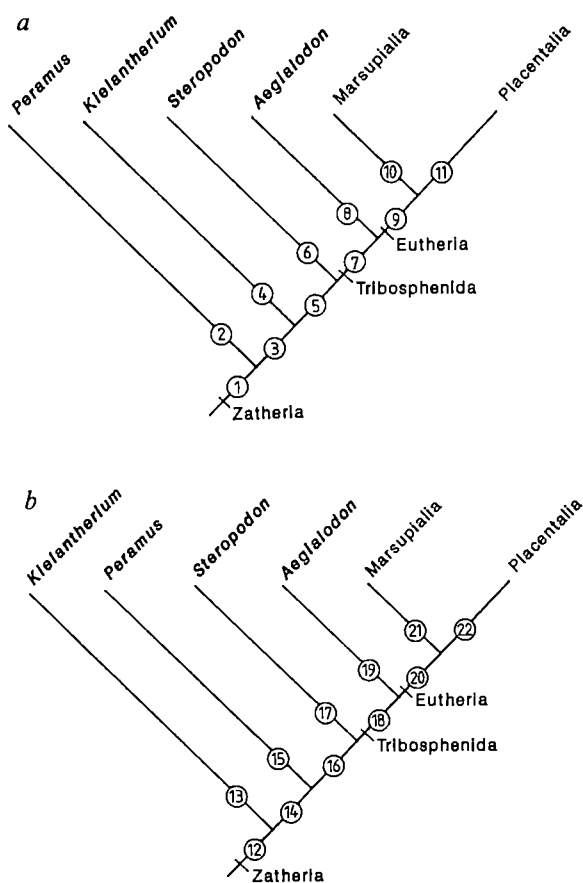

Fig. 3 The most-supported cladograms relating *Steropodon galmani*, the oldest and most plesiomorphic monotreme, to other groups of zatherian mammals. The possible relationships of monotremes to multituberculates are noted in the text. Cladogram a presumes that *Peramus tenuirostris* has four adult molars; b presumes that it has three. Potential synapomorphies are as follows: (1) reduction to four adult molars, incipiently basined talonids, stylocones reduced, anterior cingula of lower molars reduced, three talonid cusps; (2) lingually open talonid basins, premolariform first adult molar; (3) enclosed talonid basins with well-developed entocristids; (4) reduction of the entoconids as discrete cusps along the entocristids; (5) loss of postdentary bones from the lower jaw. ? loss of the meckelian groove, wide talonid basins, enlarged entoconids; (6) loss of one molar, paraconid lost from first adult molar, anterior cingula enlarged on lower molars, very wide talonid basins, hypertrophied entoconids and hypoconids, extensive pre-entocristids, loss of hypoconulids, transverse prevallid and postvallid shear; (7) protocone developed; (8) marked reduction of anterior cingula on the lower molars; (9) very wide talonid basins, enlarged protocones, transverse prevallid and postvallid shear, reduction of the postmetacristids; (10) loss of deciduous premolars, enlarged stylar cusp C, enlarged metacones, approximated entoconids and hypoconulids; (11) loss of one adult molar, reduction of stylar cusps, molariform dP4; (12) reduction to four molars, incipiently basined talonids, two talonid cusps (the hypoconid and hypoconulid), stylocones reduced, anterior cingula of lower molars reduced; (13) basined talonids with extensive pre-entocristids; (14) loss of one adult molar, entoconids developed, ? loss of meckelian groove; (15) submolariform posterior premolar, small lingual talonid basins; (16) loss of postdentary bones from the lower jaw, completely enclosed and wide talonid basins, well-developed pre-entocristids; (17) loss of the paraconid from the anterior adult molar, enlarged anterior cingula on the lower molars, hypertrophied entoconids and hypoconulids, loss of hypoconulids, transverse prevallid and postvallid shear; (18) protocone developed, pre-entocristids reduced; (19) marked reduction of anterior cingula on the lower molars; (20) same as (9); (21) same as (10) plus supernumerary molars (normally there are four adult molars in marsupials as well as a deciduous first molar); and (22) reduction of stylar cusps, molariform dP4.

absence of a paraconid on M_1 , high transverse loph-like trigonid and talonid crests, very large talonid, lack of a hypoconulid, and prominent anterior, posterior and buccal cingula are distinctive features that in combination also occur only in the isolated lower molars of the middle Miocene monotreme *Obdurodon insignis*^{3,13}. Further, the dental formula of this Lightning Ridge mammal includes three molars, the number evidently also present in *Ornithorhynchus anatinus*, the only living monotreme to retain even vestigial teeth. However, this number of molars may be a symplesiomorphic feature (see below).

The Lightning Ridge monotreme is significant in that it has relevance for interpretations of relationships among the major groups of mammals. At present, the phylogenetic position of monotremes is in considerable doubt. There are three main hypotheses in vogue: (1) monotremes (possibly with multituberculates, haramiyids and triconodonts) are prototherian mammals and as such the sister-group of the therian mammals; (2) monotremes and multituberculates are monophyletic but this group is one of three trichotomous mammal branches, the other two being the triconodonts and the therian mammals; (3) monotremes (and possibly multituberculates) are therian mammals, as opposed to the prototherian triconodonts (with docodonts) and, within Theria, they form either the sister-group of Zatheria (peramurids plus tribosphenids; refs 4, 14, 15; but see also ref. 16) or the sister-group of the Tribosphenida (Aegialodontidae plus Eutheria). We consider that the Lightning Ridge monotreme provides strongest support for the third hypothesis. Features of *S. galmani* that suggest monophyly with tribosphenid therian mammals include the apparent loss of postdentary bones, the wide and enclosed talonid basins, the enlarged entoconids and the well-developed pre-entocristids (Fig. 3).

Because of uncertainty about the molar number of the peramurid *Peramus tenuirostris*¹⁶⁻¹⁸, we are unable to decide whether peramurids or the newly described *Kielantherium*

*gobiensis*¹⁶ represents the plesiomorphic sister-group of monotremes plus tribosphenids. While Dashzeveg and Kielan-Jaworowska¹⁶ suggest that *K. gobiensis* is a tribosphenid similar to *Aegialodon dawsoni*, the presence in the latter but not the former of three well-developed talonid cusps and a wide talonid basin seems to us to be sufficient reason to question the inclusion of both forms within the same family. Pending the results of studies of monotreme occlusion, we suggest that the structure of monotremes (as evidenced by the albeit autapomorphically specialized *S. galmani*) represents an evolutionary stage between these two zatherians (Fig. 3).

The fact that distinctive monotremes were present in Australia in the early Cretaceous indicates not only the antiquity of this group but also that by this time at least some elements of Australia's fauna were exhibiting regional endemism of the sort that characterizes much of the continent's known Cenozoic faunas⁹. However, the paucity of knowledge about the early Cretaceous mammals of other continents means that we cannot exclude the possibility that monotremes also occurred on other continents in the Cretaceous.

One additional curious aspect of *S. galmani* is its large size. Not only is it the largest mammal known from the early Cretaceous, it may be one of the two largest Mesozoic mammals known, the other being the badger-sized late Cretaceous stagodontid *Didelphodon vorax*¹⁹. Overlap in body size between Mesozoic mammals and dinosaurs has not previously been recorded²⁰. The Lightning Ridge local fauna, however, includes some very small hypsilophodontid dinosaurs which were very little if at all larger than *S. galmani*.

Finally, the Lightning Ridge monotreme is heraldic because it comes from a continent that so far has failed to produce any pre-Miocene terrestrial mammals². As such, it represents a long-overdue reassurance that Australia did have an early Tertiary mammal record and that perseverance in the search will be worthwhile.

We thank Esso Australia, the State Government of New South Wales and the Director and Trustees of the Australian Museum for raising or providing funds necessary to acquire the Galman collection for the Australian Museum. We also acknowledge the contribution made by David and Alan Galman who bought and assembled a unique collection of opalized fossils from Lightning Ridge, including the *S. galmani* dentary. Michael Plane and Brian Senior helped in interpreting the geological setting of the specimen. Robert Jones helped with preparation of the specimen and John Fields, Alex Ritchie and Jenny Taylor produced the photographs. Colleagues who also contributed thoughts about the significance of the specimen include Richard Tedford, Michael Plane, Michael Woodburne, Neville Pledge, Thomas Rich, Suzanne Hand, Lyndal Dawson and Kenneth Aplin. Zophia Kielan-Jaworowska provided a cast of the important *K. gobiensis*.

Kinship, reciprocity and synergism in the evolution of social behaviour

David C. Queller

Department of Biology, Rice University, PO Box 1892, Houston, Texas 77251, USA

There are two ways to model the genetic evolution of social behaviour. Population genetic models using personal fitness¹⁻⁹ may be exact and of wide applicability, but they are often complex and assume very different forms for different kinds of social behaviour. The alternative, inclusive fitness models¹⁰⁻¹², achieves simplicity and clarity by attributing all fitness effects of a behaviour to an expanded fitness of the actor. For example, Hamilton's rule states that an altruistic behaviour will be favoured when $-c + rb > 0$, where c is the fitness cost to the altruist, b is the benefit to its partner, and r is their relatedness. But inclusive fitness results are often inexact for interactions between kin¹⁻⁵, and they do not address phenomena such as reciprocity¹³⁻¹⁵ and synergistic effects^{7,8,16} that may either be confounded with kinship or operate in its absence. Here I develop a model the results of which may be expressed in terms of either personal or inclusive fitness, and which combines the advantages of both; it is general, exact, simple and empirically useful. Hamilton's rule is shown to hold for reciprocity as well as kin selection. It fails because of synergistic effects, but this failure can be corrected through the use of coefficients of synergism, which are analogous to the coefficient of relatedness.

For simplicity, assume that all members of a diploid population interact in pairs, that each may or may not have an opportunity to aid its partner and that the genetic component of altruism is due to two alleles at a single locus, with no overdominance. Table 1 defines the random variables used in the model. Each is defined over the whole population. The phenotypic

Table 1 Random variables used in the model

- G = an individual's frequency of the altruism allele ($0, \frac{1}{2}$ or 1)
 P = an individual's phenotypic value (1 when altruistic, 0 when not)
 W = total fitness
 W_0 = fitness if aid is neither given nor received
 C = fitness cost if individual were to be altruistic (that is, if $P = 1$)
 B = fitness benefit if partner were to be altruistic (that is, if $P' = 1$)
 D = deviation from additivity of C and B if both were altruistic (that is, if $PP' = 1$)
 G', P', B', D' = an individual's partner's values of G, P, B, D

values (P, P') are defined as either 1 or 0 , where, in contrast to inclusive fitness models, the latter case applies to all individuals who did not perform the altruism, including those who had no opportunity to do so. Fitness components are also defined for all individuals, for example, C is defined, even for a non-altruist, as the cost it would incur if it were altruistic. Finally, assume that each fitness component is distributed independently of G, G', P and P' .

An individual's fitness, W , can be written as

$$W = W_0 - CP + BP' + DPP' \quad (1)$$

where multiplication by the phenotypic values ensures that the fitness components are counted only when the appropriate behaviours are performed. Assuming a fair meiosis, Price's selection equation¹⁷ shows that $\Delta \bar{G} = \text{Cov}(G, W) / \bar{W}$, so the

altruism allele is favoured ($\Delta \bar{G}$ positive) when $\text{Cov}(G, W) > 0$. Substituting for W from equation (1) and splitting into four terms yields

$$\text{Cov}(G, W_0) - \text{Cov}(G, CP) + \text{Cov}(G, BP') + \text{Cov}(G, DPP') > 0 \quad (2)$$

Since W_0 , C , B and D are distributed independently of G , G' , P and P' , the first term is zero and the remainder may be rewritten as $-\bar{c} \cdot \text{Cov}(G, P) + \bar{b} \cdot \text{Cov}(G, P') + \bar{d} \cdot \text{Cov}(G, PP') > 0$, where \bar{c} , \bar{b} and \bar{d} are the sample means of C , B and D .

The mean fitness effects have now been extracted from the covariances that embody the population structure. Dividing through by $\text{Cov}(G, P)$ yields:

$$-\bar{c} + \bar{b} \cdot \frac{\text{Cov}(G, P')}{\text{Cov}(G, P)} + \bar{d} \cdot \frac{\text{Cov}(G, PP')}{\text{Cov}(G, P)} > 0 \quad (3)$$

This is still a personal fitness formulation since all fitness effects are assigned to the individual affected rather than to the one responsible for the effect. An inclusive fitness form is obtained by rewriting condition (2) as $\text{Cov}(G, W_0) + \text{Cov}(G, CP) + \text{Cov}(G', B'P) + \text{Cov}(G', D'P'P) > 0$. The same set of interactions are scored for genotype, phenotype and fitness effect. In the third and fourth terms we have simply switched the arbitrary labels designating when an individual is considered as self and when as someone else's partner. Mathematically this amounts to reordering the terms within the covariance, leaving the total unchanged. Proceeding as before now yields

$$-\bar{c}' + \bar{b}' \cdot \frac{\text{Cov}(G', P)}{\text{Cov}(G, P)} + \bar{d}' \cdot \frac{\text{Cov}(G', P'P)}{\text{Cov}(G, P)} > 0 \quad (4)$$

We now have equivalent results from the viewpoints of personal fitness (condition 3) and inclusive fitness (condition 4). When costs and benefits are additive, $\bar{d} = \bar{d}' = 0$, and the third terms disappear. What remains is Hamilton's rule, using covariance measures of relatedness previously proposed by Orlove and Wood¹⁸ (condition 3) and by Michod and Hamilton¹⁹ (condition 4). Here, however, these measures are taken over all individuals in the population, not just those with an opportunity to perform altruism, and this minor change makes the two measures equivalent.

These relatedness coefficients actually measure more than pedigree connections. The derivation is unchanged for altruism expressed in a conditional manner: be altruistic to an untested partner; otherwise, behave towards the partner as he behaved towards you. This reciprocal altruism strategy can be selected for the same reason as altruism towards kin: covariance between the performance of the behaviour and the recipient's frequency of the altruism allele. With reciprocal altruism a positive covariance arises when a partner's prior behaviour serves as a reliable indicator of possession of the reciprocity genes.

The third terms of conditions (3) and (4) correct Hamilton's rule for non-additivity. They consist of the product of the average deviation effect, \bar{d} , and a population structure coefficient. I will call these s coefficients, or coefficients of synergism, because they depend on the joint behaviour of both partners (PP'). In every other respect they are the same as the r coefficients measuring relatedness and reciprocity; both depend on a covariance between the behaviour(s) causing a fitness effect and the genes of the individual receiving it. These s coefficients are positive, even when interactants are not relatives (though they approach zero for very low P and P'), so that the sign of \bar{d} alone determines the direction of error in Hamilton's rule. Since relatedness is not required, the third term is best viewed as being due to something other than kin selection: a form of trait group selection⁹ or, to use a more evocative term, synergistic selection¹⁶. In this view, Hamilton's rule is correct for pure kin selection (and, as shown above, reciprocal altruism); its failure is caused by a distinct process.

A variety of biological phenomena can be represented by the D term²⁰. Several examples are given below. In each, D represents some combined effect of two altruists, acting either

sequentially or simultaneously, beyond their summed effects if they acted alone.

For behaviours in which costs and benefits take the form of successively altered survival probabilities, such as warning calls, a multiplicative fitness model is appropriate²¹. If we let the base fitness be unity, the fitness of an individual receiving both cost and benefit is not $1 - C + B$, but $(1 - C)(1 + B)$ or $1 - C + B - BC$, so that $D = -BC$. The negative deviation from additivity means that altruism will be harder to select than predicted by Hamilton's rule, as other models have shown^{4,5}. In effect, benefits are squandered when the recipient dies because of its own altruism.

A distasteful insect with warning coloration runs an increased risk of being seen and eaten by a predator. This cost may be compensated if the bad taste causes the predator to avoid its victim's neighbours²². A general avoidance of neighbours, regardless of their coloration, would be represented by B , and this could select for warning coloration if neighbours tend to be related. But any additional avoidance of only those neighbours with warning coloration must be represented by a positive D because this gain applies only to those who play the same strategy as the altruist.

Male lions may cooperate in taking over or retaining a pride²³. In searching for a partner, a cooperative lion may incur some cost, C , whether or not the potential partner actually cooperates. The fitness gain, however, applies only if cooperation does ensue ($PP' = 1$), and is therefore represented not by B , but by a synergistic D . For both lion cooperation and warning coloration, the positive D means Hamilton's rule underestimates the ease with which these traits are selected. In fact, if the altruistic trait can reach non-zero levels by drift, the s coefficient will be positive even in the absence of relatedness, so that a positive D could sometimes select for altruism by itself.

The model is quite general. It is not restricted to altruistic behaviours, since B and C may be assigned negative values. Additional synergistic effects can be incorporated by adding terms to the fitness decomposition in equation (1). For example, if three altruists ($P = P' = P'' = 1$) cause some additional effect, E , beyond that caused by two, the added term would be $EPP'P''$. The starting point of the model, Price's equation, holds for any mating system and is easily adjusted for haplodiploidy. It is also valid for any linear function of any number of alleles at any number of loci¹⁷. Thus, G and G' may be interpreted as the breeding value for the altruistic behaviour. Since this value can be estimated through breeding experiments²⁴, the model should be useful in empirical studies.

Plasticity of functional epithelial polarity

George J. Schwartz*, Jonathan Barasch† & Qais Al-Awqati†

The fundamental characteristics that allow vectorial transport across an epithelial cell are the differential sorting and insertion of transport proteins either in the apical or the basolateral plasma membrane, and the preferential association of endocytosis and exocytosis with one or the other pole of the cell. Asymmetrical cellular structure and function, being manifestations of terminal differentiation, might be expected to be predetermined and invariant. Here we show that the polarity of transepithelial H^+ transport, endocytosis and exocytosis in kidney can be reversed by environmental stimuli. The HCO_3^- -secreting cell in the cortical collecting tubule is found to be an intercalated cell possessing a Cl^-/HCO_3^- exchanger in the apical membrane and proton pumps in endocytic vesicles that fuse with the basolateral membrane; the H^+ -secreting cell in the medullary collecting tubule has these transport functions on the opposite membranes. Further, the HCO_3^- -secreting cell can be induced to change its functional polarity to that of the H^+ -secreting cell by acid-loading the animal.

We identified a subset of cells in isolated cortical collecting tubules using the mitochondrial accumulation of the fluorescent cation 3,3'-dipentylloxycarbocyanine (Di-O-C₅(3)) (Fig. 1a). These mitochondrion-rich cells are enriched in carbonic anhydrase and transport protons^{1,2}; that is, they are the intercalated cells. We stained cortical collecting tubules with 6-carboxyfluorescein diacetate; this is a permeant nonfluorescent precursor of the pH-sensitive dye 6-carboxyfluorescein which is released by cytoplasmic esterases such as carbonic anhydrase, so these cells will preferentially accumulate the dye (Fig. 1b). There were 100–150 intercalated cells per mm of tubule, accounting for about 25% of all the cells in this segment (L. M. Satlin and G.J.S., unpublished observations). The cytoplasmic pH (pH_i) of the intercalated cell, measured by excitation ratio microspectrofluorometry^{2,4}, was on average 0.4 pH units higher than that of the principal cell. When collecting tubules were perfused with fluorescent macromolecules, only 5–10% of the intercalated cells in the cortical tubule, but most of those in the medullary segment, endocytosed the fluorophores (Fig. 1c–e)³. Since the medullary collecting tubule secretes H^+ whereas the cortical collecting tubule secretes HCO_3^- (Table 1), it is likely that the intercalated cell showing luminal endocytosis is the H^+ -secreting cell, while that lacking it secretes HCO_3^- .

To test this directly, we removed chloride from the basolateral solution and measured pH_i in individual intercalated cells simultaneously identified as those showing or not showing endocytosis by the uptake of rhodamine-bovine serum albumin (BSA) (see Table 1 legend). Removal of basolateral chloride stimulated HCO_3^- secretion in the cortical collecting tubule and inhibited H^+ secretion (HCO_3^- absorption) in the medullary collecting tubule (Table 1). It also increased the cell pH by 0.2 ± 0.1 units in both cortical and medullary intercalated cells that had endocytosed rhodamine-BSA from the lumen (Table 1). The increased cellular pH and decreased H^+ secretion in medullary collecting tubules indicate that the lumenally endocytosing cell has a basolateral Cl^-/HCO_3^- exchanger and is the H^+ -secreting cell. In the cells that did not endocytose rhodamine-BSA, removal of basolateral Cl^- decreased cell pH by 0.4 ± 0.1 pH units (Table 1). As this manoeuvre stimulated HCO_3^- secretion, the reduction in pH_i indicates that this cell is the HCO_3^- -secreting cell, with a Cl^-/HCO_3^- exchanger located in the luminal membrane.

Table 1 Net HCO_3^- transport ($J_{HCO_3^-}$) and cell pH (pH_i) in individually identified intercalated cells of isolated perfused cortical and medullary collecting tubules

	$J_{HCO_3^-}$ ($\mu\text{mol min}^{-1}$ mm^{-1})	Luminal endocytosis	pH_i No luminal endocytosis
Cortical collecting tubule			
Control	-3.3 ± 1.6 $n = 13$	7.23 ± 0.06 $n = 7$	7.34 ± 0.09 $n = 7$
Cl^- -free bath	$-12.0 \pm 2.3^\dagger$	$7.40 \pm 0.09^*$	$6.96 \pm 0.13^*$
Medullary collecting tubule			
Control	9.1 ± 1.6 $n = 5$	7.14 ± 0.07 $n = 5$	—
Cl^- -free bath	$2.1 \pm 1.6^*$	$7.33 \pm 0.04^\dagger$	—

One to four cells were studied in each perfused tubule to provide a mean for each animal. Net fluid absorption in four cortical collecting tubules perfused and bathed in identical solutions was negligible (control = 0.023 ± 0.024 ; Cl^- -free bath = 0.022 ± 0.027 $\text{nl min}^{-1} \text{mm}^{-1}$, $P > 0.5$). The tubules were perfused at $1-2$ $\text{nl min}^{-1} \text{mm}^{-1}$. Bicarbonate concentration in nl samples was measured by microcalorimetry¹⁰ and net bicarbonate transport was calculated from the product of the difference in HCO_3^- concentration between perfused and collected fluids and the flow rate, and normalized to mm of tubular length. All experiments were done at 38°C and used an artificial solution (290 ± 1 mosmol per kg) containing (in mM): NaCl (114), $NaHCO_3$ (25), K_2HPO_4 (2.5), $CaCl_2$ (2.0), $MgSO_4$ (1.2), glucose (5.5), L-alanine (6.0), Na-lactate (4.0) and citrate (1.0); it was gassed with 95% $O_2/5\%$ CO_2 to yield a pH of 7.4. At least three collections of tubular fluid were obtained for measurement of total CO_2 . Plus values denote bicarbonate absorption (H^+ secretion) while negative values denote bicarbonate secretion. Cell pH was measured in individually identified cells using 20–30 μM 6-carboxyfluorescein diacetate in the bath to load the cells for 5 min with 6-carboxyfluorescein. Simultaneously, the lumen was perfused with the same artificial solution containing rhodamine-BSA as a fluorescent macromolecule at $0.5-1$ mg ml^{-1} . The cells that endocytosed the fluorescent macromolecule, considered to be H^+ -secreting cells, appeared red under the rhodamine filter cassette (Fig. 1d, e) and bright green under the fluorescein filter block (Fig. 1b). Those cells which did not endocytose rhodamine from the lumen appeared bright green under the fluorescein filter cassette and showed no red staining with the rhodamine filters. Each cell was identified as rhodamine-positive or -negative and centred in the microscope photometer aperture. The filter cassette was then changed to fluorescein, the single cell was excited at 450 and 490 nm, and the emission was recorded at 535 nm in a Farrand microspectrofluorometer via the photometer attached to the camera port of the inverted microscope. As there were so few cells that did not endocytose rhodamine-BSA in the medullary collecting duct, we did not study such cells in that segment. Because the pH sensitivity of 6-carboxyfluorescein tends to saturate at pH values > 7.3 , these isolated tubules were studied at a pCO_2 of 50–55 mm Hg. This mild respiratory acidosis slightly decreased the cell pH. At the end of each experiment, the tubule was exposed to 100 μM of the electrogenic proton ionophore CCCP (carbonyl cyanide *p*-chlorophenyl hydrazone) in 150 mM KCl plus 10 mM phosphate buffer. This combination depolarized the cell and clamped the pH of the cytoplasm to that of the bath. The pH of the bath was compared with that measured fluorimetrically in 5–15 cells of the clamped tubules. The recorded pH values were obtained from a calibration curve over a pH range of 5.5–7.5 in the same calibration buffer. The fluorescence intensity of the 6-carboxyfluorescein-containing extracellular calibration solution was chosen to be approximately the same as the intensity of the cells studied *in vitro*, $\sim 1-2$ μM . The average pH difference between the fluorimetric cellular pH and the pH of the bath as measured by a microelectrode was 0.02 ± 0.03 units ($n = 10$ tubules) and was not a significant difference.

* $P < 0.05$; † $P < 0.01$ (Cl^- -free bath versus control). Mean \pm s.e., n = number of animals.

Secretion of HCO_3^- by a lumenally located Cl^-/HCO_3^- exchanger implies that a proton-translocating H^+ -ATPase exists at the basolateral membrane. Such proton pumps are packaged in endocytic vesicles, as we have shown in the H^+ -secreting cells²⁻⁴. To demonstrate basolateral endocytosis into acid vesicles, fluoresceinated dextran (relative molecular mass 70,000) was added to the basolateral medium of collagenase-treated cortical collecting tubules. Some, but not all, intercalated cells endocytosed the macromolecules into vesicles (Fig. 1f) that maintained an intravesicular pH of 6.0 ± 0.2 ($n = 14$ tubules, with 5–6 cells measured per tubule), similar to that found previously in cells endocytosing fluorescein-dextran from the lumen^{2,3}. By measuring total cellular fluorescence in 6 tubules (4–5 cells studied per tubule), we found that increasing ambient pCO_2 induced the exocytotic release of $40 \pm 3\%$ of the basolaterally endocytosed fluorescein-dextran (or the pH-insensitive dye Lucifer yellow), similar to results found for the lumenally endocytosing cell³.

To confirm the presence of basolateral endocytosis, we exposed collagenase-treated cortical collecting tubules to horse-

Fig. 1 *a*, Isolated cortical collecting tubule incubated for 5 min in 50 nM Di-O-C₃(3), a fluorescent cation which accumulates in mitochondria. At this low concentration of the dye the reticular, perinuclear pattern is seen only in some cells, the mitochondrion-rich (intercalated) cells $\times 200$. *b*, Isolated cortical collecting tubule incubated for 5 min in 20 μ M 6-carboxy fluorescein diacetate. Bright fluorescence is seen in the mitochondrion-rich cells. These cells are enriched in carbonic anhydrase, a potent esterase, and thus preferentially take up this dye. Further, as these cells are more alkaline, the dye will appear brighter than in the other cells. $\times 200$. *c, d*, Cortical collecting tubules perfused for 10 min with rhodamine-BSA (1 mg ml⁻¹) and then washed free of luminal fluorophore. In *c*, using Hoffman modulation contrast optics, note the presence of intercalated cells with a characteristic bulging surface at the top right and bottom right. *d*, The same field using epifluorescence optics. Only the bottom right cells have internalized the fluorophore. The pattern of fluorescence is diffuse, with negative nuclear staining. Because of the enrichment of the cells with vesicles and consequent light scattering, it is difficult to resolve individual vesicles. $\times 300$. *e*, Fluorescence micrograph of a medullary collecting tubule perfused in a similar manner to that of *d*. Endocytosis of the marker is seen in many more cells than in the cortical collecting tubule in *d*. $\times 200$. *f*, Isolated perfused cortical collecting tubule incubated for 20 min with 3 mg ml⁻¹ Lucifer yellow in the basolateral bathing medium. After extensive washing the tubule was mounted between two coverslips and photographed. A punctate uptake of this small non-permanent dye is seen in some cells. $\times 500$. *g*, Isolated cortical collecting tubule incubated for 2 min in 10 μ M acridine orange. This weak base is concentrated in acid vesicles and its emission spectrum undergoes a redshift at high concentration. The cell numbered 1 shows a concentration of sub-apical vesicles with no basolateral acid vesicles, suggesting that it is the H⁺-secreting cell. Cell 2 (probably a HCO₃⁻-secreting cell) has many sub-apical and basolateral vesicles. Addition of 5 μ M nigericin, a K⁺H⁺ exchange ionophore, abolished the orange staining in the vesicles, indicating that the dye accumulated in these vesicles because of the presence of a pH gradient across their membranes. $\times 500$. *h, i*, A cortical collecting tubule perfused at 38 °C for 10 min with rhodamine-BSA (1 mg ml⁻¹), washed free of the dye, cooled to 9 °C for 3 min and perfused with fluorescein-conjugated peanut lectin (0.5 mg ml⁻¹). After washout of fluorescein lectin, the tubule was mounted between two coverslips and photographed at $\times 500$. *h*, Note two patterns of fluorescence, one appearing diffuse with a negative nuclear stain while the other shows sharper edges characteristic of surface binding. *i*, The same field observed with rhodamine filters. Note endocytosis of the macromolecules only in the cell that shows a diffuse pattern and negative nuclear stain in *h*. *j*, Collecting tubule isolated from the ampulla of the newborn rabbit kidney, fixed with 2% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4) containing 10 μ g ml⁻¹ Hoechst 33258, the fluorescent chromatin-binding stain. After 1 h of exposure the segment was mounted between two coverslips. Note that the chromosomes are condensed in the polar positions of anaphase. $\times 500$. Tubules isolated as described in Table 1.

Fig. 2 Electron microscopy of cortical collecting tubules in intact kidneys (*a, b*) and in isolated tubules incubated for 10 min in 2% horseradish peroxidase (type VI, Sigma) (*c, d*). Tubules were fixed with 4% glutaraldehyde and post-fixed with 1% OsO_4 . They were then reacted with the diaminobenzidine/glucose/glucose oxidase system of Itoh *et al.*¹¹ for 30 min after pretreatment with 0.1% CoCl_2 . Two types of intercalated (mitochondria-rich) cells are seen. In *a* and *c* apical vesicles are surmounted by a dense cytoskeletal meshwork (*a*, arrowhead) and coated endocytic vesicles and omega figures are found along the basolateral membrane (*a*, inset). In *b* and *d* the apical cytoplasm is less dense and fusions between the apical vesicles and luminal membrane can be seen. Perfusion of the basolateral surface with horseradish peroxidase in isolated tubules for 10 min (*c, d*) showed considerable basolateral endocytosis in the mitochondria-rich cells having apical cytoskeletal caps (*c*, arrowheads) but no such uptake was found in the other apical vesicle-rich cell (*d*). Longer periods of exposure to horseradish peroxidase resulted in uptake of the marker in all cells. Hence, cell *c* has a higher rate of basolateral endocytosis than the other cells. bl, Basolateral; L, luminal. Scale bar, 1 μm ; inset in *a*, $\times 48,000$.

radish peroxidase from the basolateral side only. Electron microscopy revealed at least two types of intercalated cells⁵ (Fig. 2). Only one type showed basolateral uptake of horseradish peroxidase (compare Fig. 2*c* and *d*). The cells that endocytosed horseradish peroxidase contained large numbers of sub-apical vesicles (Fig. 2*a, c*), separated from the plasmalemma by a dense 'mat' of fibrillar cytoskeletal matrix (Fig. 2*a*). Also apparent were many endo-exocytic (omega) figures and coated vesicles at the basolateral membrane (Fig. 2*a*, inset). In the other type of intercalated cell these omega figures and coated vesicles occurred predominantly at the apical membrane (Fig. 2*b, d*). Such coated vesicles (probably clathrin-coated vesicles) are known to contain the H^+ -ATPase⁶⁻⁸. Both sub-apical and basolateral vesicles were acidic, as shown by the accumulation of the weak base acridine orange (Fig. 1*g*). Cell 2 in Fig. 1*g* is probably the HCO_3^- -secreting cell containing apical and basolateral acid vesicles; cell 1 is probably an H^+ -secreting cell containing a large sub-apical concentration of vesicles. The principal cells did not contain many acid vesicles.

When animals were given a chronic acid load, the transport properties of cortical collecting tubules removed 24 h later and perfused *in vitro* at pH 7.4 were converted from HCO_3^- secretion

to H^+ secretion (Table 2). This was accompanied by a large increase in the number of H^+ -secreting cells (that is, cells showing luminal endocytosis) (Table 2). To test whether the increased H^+ secretion was due to a conversion of the polarity of the HCO_3^- -secreting cell or to a proliferation in the H^+ -secreting cell, we counted both H^+ - and HCO_3^- -secreting cells. Intercalated cells were identified by their ability to bind peanut lectin⁹. When fluorescent peanut lectin was perfused into the lumen of the cortical collecting tubule, two staining patterns emerged—bright surface staining with sharp edges (Fig. 1*h*), crescentic in perfused tubules, and more diffuse staining reminiscent of the endocytic pattern, with the nucleus observed as an unstained region (Fig. 1*h*). When the tubule was perfused with macromolecules labelled by a different fluorophore, only the cells with diffuse lectin staining endocytosed the macromolecules (compare Fig. 1*h* and *i*). Chronic acid loading did not increase the total number of intercalated cells per mm of tubule (control 129 ± 5 , $n = 15$ tubules; acid-loaded 137 ± 6 , $n = 10$ tubules, $P > 0.5$). Rather, the increase in the number of H^+ -secreting cells was accompanied by an equivalent decrease in the number of HCO_3^- -secreting cells (Table 2). Further, if the 10-fold increase in the number of H^+ -secreting cells seen after

Table 2 Effects of acid loading on isolated perfused cortical collecting tubules in rabbits

	$J_{\text{HCO}_3^-}$ ($\mu\text{mol min}^{-1}$ mm^{-1})	Potential difference (mV)	H^+ - secreting cells	HCO_3^- - secreting cells
Control	-1.6 ± 0.5 (4)	-13 ± 3 (4)	7 ± 2 (15)	122 ± 4 (15)
Acid-loaded	5.4 ± 0.8 (7)†	-5 ± 2 (7)*	74 ± 10 (10)†	63 ± 11 (10)†

Tubules were from control rabbits or from rabbits given NH_4Cl (10–20 mequiv per kg per day by gavage) for 5 ± 1 days. Cell counts for luminal endocytosis (10 control and 9 acid-loaded rabbits) were obtained by perfusing each tubule for 10 min at 38°C with $0.5\text{--}1\text{ mg ml}^{-1}$ fluorescein-dextran³ dissolved in a bicarbonate-free solution (290 ± 1 mosmol per kg) containing (in mM): NaCl (139), K_2HPO_4 (2.5), CaCl_2 (2.0), MgSO_4 (1.2), glucose (5.5), L-alanine (6.0), Na-lactate (4.0) and $\text{Na}_3\text{-citrate}$ (1.0); pH was 7.4. The chamber was then cooled to $9\text{--}12^\circ\text{C}$ for 5 min, after which rhodamine-peanut agglutinin was perfused in the lumen for 2–3 min. The solution was washed out with cold fluorophore-free solution and the tubule was warmed to room temperature for study by epifluorescence microscopy. At least three $250\text{-}\mu\text{m}$ segments of each cortical collecting tubule were examined for numbers of green, fluorescein-positive or luminally endocytosing cells, and for red or lectin-binding cells. Despite the cooling of the specimen chamber, it was not always possible to rule out endocytosis of peanut lectin by the acid-secreting cells, which could lead to an overestimate of the number of the HCO_3^- -secreting cells. The total number of cells per mm was determined by counting nuclei in duplicate at $\times 1,000$ over three to six $50\text{-}\mu\text{m}$ lengths of each cortical collecting tubule that was fixed according to Fig. 1j legend. The total number of cells per mm of tubule was similar in both groups: control, 561 ± 8 ; acid-loaded, 543 ± 11 ($P > 0.2$). Bicarbonate transport was measured in a second perfused cortical collecting duct isolated from the same kidney slice. Transepithelial voltage (PD) was measured using the luminal pipette as an electrode and the bath solution as a reference³. The three to five measurements of potential difference were made at the time of each collection of tubular fluid for determination of bicarbonate concentration. Both luminal and bathing solutions were identical (290 ± 1 mosmol per kg) and contained (in mM): NaCl (114), NaHCO_3 (25), K_2HPO_4 (2.5), CaCl_2 (2.0), MgSO_4 (1.2), glucose (5.5), L-alanine (6.0), Na-lactate (4.0) and $\text{Na}_3\text{-citrate}$ (1.0); they were gassed with 95% $\text{O}_2/5\%$ CO_2 to yield a pH of 7.4. Bicarbonate transport was measured by microcalorimetry as described in Table 1 legend. Ammonium chloride administration caused a chronic acidosis in most rabbits, the mean total CO_2 in the plasma being 22 ± 2 mM compared with 28 ± 1 mM in controls. Moreover, the urine pH was lower: 6.1 ± 0.4 in ammonium chloride-loaded rabbits and 8.5 ± 1.4 in control animals. Note that the administration of ammonium chloride did not necessarily cause a chronic acidosis in all animals, because the kidneys were markedly stimulated to increase acid excretion. Some animals showed normal levels of total CO_2 , yet the tubules from the animals absorbed bicarbonate at high rates and the number of cells that could endocytose fluorescent dextran from the lumen was markedly higher than in control animals.

* $P < 0.05$; † $P < 0.01$ (acid-loaded versus control). Mean \pm s.e. (number of tubules).

a few days of acid loading was caused by cellular proliferation, mitotic figures should be apparent. We saw such figures (using the dye Hoechst 33258) only in the ampulla of the collecting duct of newborn rabbits (Fig. 1j). There was only one mitotic figure in 27 tubules from 5 control animals (15,150 cells) and none in 70 tubules from 10 acid-loaded animals (38,170 cells). To examine the possibility that mitosis occurred early in acid loading, we studied eight tubules (4,280 cells) removed from animals after 1 day of acid loading, but found no mitotic figures even though the number of H^+ -secreting cells had increased three to fivefold. Thus, the observed increase in the number of H^+ -secreting cells is caused by a reversal of the functional polarity of the HCO_3^- -secreting cell, and this reversal accounts for the conversion of the tubule from HCO_3^- secretion to H^+ secretion.

The conversion of HCO_3^- -secreting cells to acid-secreting cells requires not only relocation or activation/inactivation of the transporting elements (the proton ATPase, the parallel Cl^- channel and the $\text{Cl}^-/\text{HCO}_3^-$ exchanger) at the appropriate pole, but also remodelling of the cytoplasm to allow exocytosis and endocytosis at the apical pole of the cell and to inhibit them at the basolateral domain (Fig. 2). Such responses must also be stable for at least 24 h.

Upstream sequences modulate the internal promoter of the human 7SL RNA gene

Elisabetta Ullu* & Alan M. Weiner

Department of Molecular Biophysics and Biochemistry,
Yale University, PO Box 3333, New Haven, Connecticut 06510, USA

The human genome is rich in sequences which are structurally related to the 7SL RNA component of the signal recognition particle¹. The 7SL DNA sequence family consists of four 7SL genes², 500 7SL pseudogenes² (which are truncated at one or both ends of the 7SL sequence) and 500,000 *Alu* sequences^{3–5}. Both 7SL genes² and *Alu* elements^{6–8} are transcribed by RNA polymerase III, and we show here that the internal 7SL promoter lies within the *Alu*-like part of the 7SL gene. Why then does RNA polymerase III transcribe the few 7SL genes so efficiently, while transcripts from the far more abundant *Alu* elements are not readily detectable^{9–11}? We find that a human 7SL gene and a synthetic *Alu* sequence derived from it are expressed 50–100-fold more efficiently *in vitro* than either a representative *Alu* element or two 7SL pseudogenes. 5' Deletion and insertion mutants of the 7SL gene demonstrate that, in conjunction with the internal promoter, the first 37 nucleotides upstream from the transcription start site are essential for efficient and accurate initiation *in vitro*. We suggest that the genomic sequences upstream from most *Alu* elements and 7SL pseudogenes do not contain this element, and consequently that only a small subset of such sequences can be transcribed *in vivo*. This may help to explain the homogeneity of the *Alu* family within each mammalian genome, as well as the species-specific differences between mammalian *Alu* families.

To determine which sequences in the human 7SL gene are important for expression, we compared the *in vitro* transcription of one of the four human 7SL genes, 7L30.1 (ref. 2) (Fig. 1A, lane 30), two 3'-truncated 7SL pseudogenes, 7L28 and 7LEM1 (ref. 2) (lanes 28 and EM1), and a pBR322 derivative of the human 7SL cDNA clone p7L1 (ref. 12), called p7L1-bis (lane 1; see Fig. 1B for the structures of the clones). Although all the 7SL clones were transcribed, the wild-type 7SL gene was 50–100 times more efficient than the other templates. The gene-pseudogene fusions (lanes 30–28 and 28–30) show that the sequences required for efficient transcription lie predominantly to the 5' side of the *Sma*I site in the 7SL gene (Fig. 1B). Transcription of the 7SL cDNA clone p7L1-bis proves that the 7SL coding region contains an internal promoter.

We also compared the transcription of a cloned *Alu* element with that of the 7SL gene (Fig. 1C). For this analysis we chose the *Alu* sequence located upstream from the human γ -globin gene, which is transcribed *in vitro* to yield a major transcript of ~575 nucleotides⁶. Since full activity of the 7SL promoter² requires an unusually low concentration of Mg^{2+} , the *Alu* and 7SL gene templates were assayed over a range of Mg^{2+} concentrations. The optimum for the 7SL gene was 1 mM Mg^{2+} ,

* Present address: Department of Internal Medicine, Yale University, PO Box 3333, New Haven, Connecticut 06510, USA.

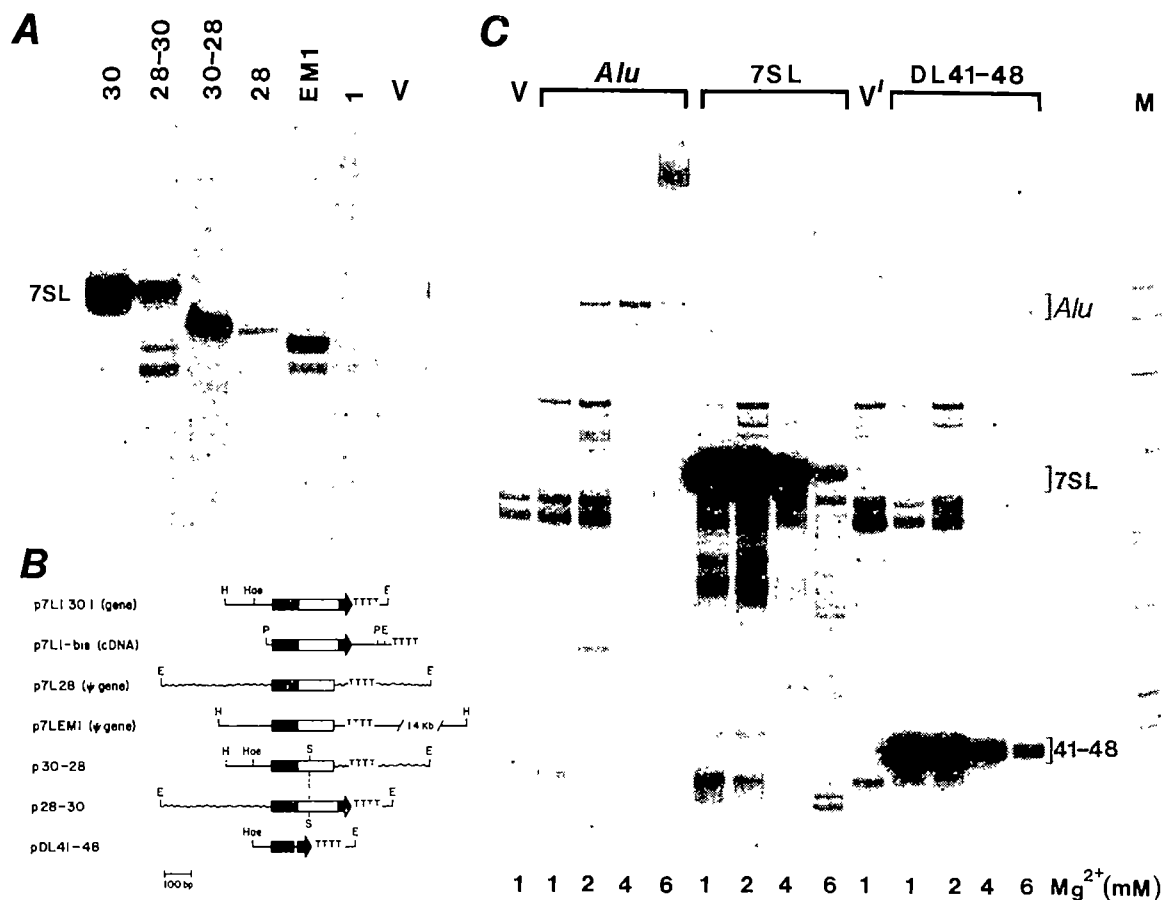

Fig. 1 **A**, The products of *in vitro* transcription of gene 7L30.1² (lane 30, 7SL RNA-300 nucleotides; nt), 3'-truncated pseudogenes 7L28 (lane 28, 7L28 RNA ~275 nt) and 7LEM1 (lane EM1, 7LEM1 RNA 265 nt)², 7L1-bis cDNA (lane 1, 7L1 RNA ~440 nt), recombinants 7L30-28 (lane 30-28) and 7L28-30 (lane 28-30) and pUC13 vector DNA (lane V). Transcription of 7SL templates in a HeLa cell nuclear extract³¹, fractionation and purification of the transcripts were carried out as described previously². To quantitate RNA synthesis, labelled RNA bands were detected by autoradiography, excised from the gel and Cherenkov radiation was counted. In different experiments the yield of ³²P radioactivity per band was: 7L30.1 RNA, 2.5–4 × 10⁵ c.p.m.; 7L28 RNA, 2–4 × 10⁵ c.p.m.; 7LEM1 RNA, 5–10 × 10⁵ c.p.m.; 7L1-bis RNA 2–4 × 10⁵ c.p.m.; 7L30-28 RNA, 1.5–2 × 10⁵ c.p.m.; 7L28-30 RNA 5–10 × 10⁵ c.p.m. As assayed by T1 RNAase fingerprinting, the major transcripts derived from all templates initiated at or near the normal start site² and terminated at a run of four or more T residues in the template DNA (see **B**; data not shown). **B**, Schematic representation of the 7SL clones used for *in vitro* transcription. p7L30.1² contains human 7SL gene 7L30.1 including the entire coding region plus ~180 base pairs (bp) of 5'-flanking and 30 bp of 3'-flanking DNA in pUC13. p7L28 and p7LEM1 are pUC13 plasmid subclones derived from 7SL pseudogenes 7L28 and 7LEM1². Both pseudogenes are colinear with the 7SL coding sequence up to position 235, but their genomic context is different. p7L1-bis contains a complete cDNA copy of human 7SL RNA from clone p7L1¹² inserted into pBR322 so that the T₃ oligonucleotide at vector position 4,324 is immediately 3' to the 7SL coding region. Plasmid subclones p7L30.1 and p7L28 were recombined using the unique *Sma*I site at position 143 in the 7SL coding region. The DNA fragment corresponding to the 5' half of the gene was ligated to the 3' fragment of the 7L28 pseudogene to create p7L30-28, and the 5' half of the pseudogene was ligated to the 3' half of the gene to create p7L28-30. Plasmid pDL41-48 is a recombinant derived from p7L30.1-5'-66 (see below) in which the nucleotides between positions 85 and 248 have been deleted and substituted with an 8-nt *Xho*I linker. The arrows represent the various 7SL DNAs and indicate the direction of transcription; the shaded areas represent the *Alu* sequence of 7SL DNA^{4,12}; H, *Hind*III; E, *Eco*RI; S, the *Sma* site used to recombine p7L30.1 and p7L28; P, *Pst*I; Hae, *Hae*III; TTTT, indicates the position of the transcription terminator³². **C**, Products of *in vitro* transcription of the 7SL gene 7L30.1 (lanes 7SL), clone pBS2⁶ (lanes *Alu*) which contains the *Alu* sequence upstream from the human γ -globin gene, and of clone pDL41-48 (lanes 41-48) as a function of varying Mg^{2+} concentration. The amount of exogenous Mg^{2+} added is indicated below each lane. V, pBR322 transcripts; V', pUC13 transcripts; M, end-labelled *Hpa*II DNA fragments of pBR322 as relative molecular mass markers. The yield of transcripts from clone pBS2 was comparable to that from pseudogene 7L28. The human genomic *Alu* clone pEB77 (ref. 33) and the monkey *Alu* clone p7.01 (ref. 34) gave a similar result.

while the *Alu* sequence was transcribed best at 4 mM Mg^{2+} . Even when the transcription activities of the two templates were compared at their respective Mg^{2+} optima, the 7SL gene was at least 100 times more active than the genomic *Alu* clone. A similar result was obtained with two additional genomic *Alu* sequences (see Fig. 1C legend). Taken together, these results suggest that either the 5'-flanking DNA or the central non-*Alu* portion of the 7SL coding region (the S sequence¹²) might be responsible for the high level of 7SL gene transcription.

To test whether sequences in the non-*Alu* portion of the 7SL coding region are required for efficient transcription, we deleted the S sequence from the 7SL gene. This synthetic *Alu* sequence (pDL41-48, Fig. 1B) produced the expected shorter transcript

of ~140 nucleotides (Fig. 1C, lanes DL41-48), was as active as the 7SL gene itself, and exhibited the same Mg^{2+} optimum. We conclude that the 5'-flanking sequence of gene 7L30.1 is likely to be responsible for its high expression, and that the internal control region must reside within the *Alu*-like parts of 7SL DNA because the S sequence is not required for transcription *in vitro*.

Next, we constructed a series of 7SL genes with progressive deletions of 5'-flanking DNA (Fig. 2A). Deletion of sequences downstream of nucleotide -37 had two effects on *in vitro* transcription (Fig. 2B). First, mutant 7SL genes with less than 37 base pairs of 5'-flanking sequence displayed a significant reduction in activity. For instance, the 5'-2 mutant, which contains only the 7SL coding sequence plus 30 nucleotides of 3'-flanking

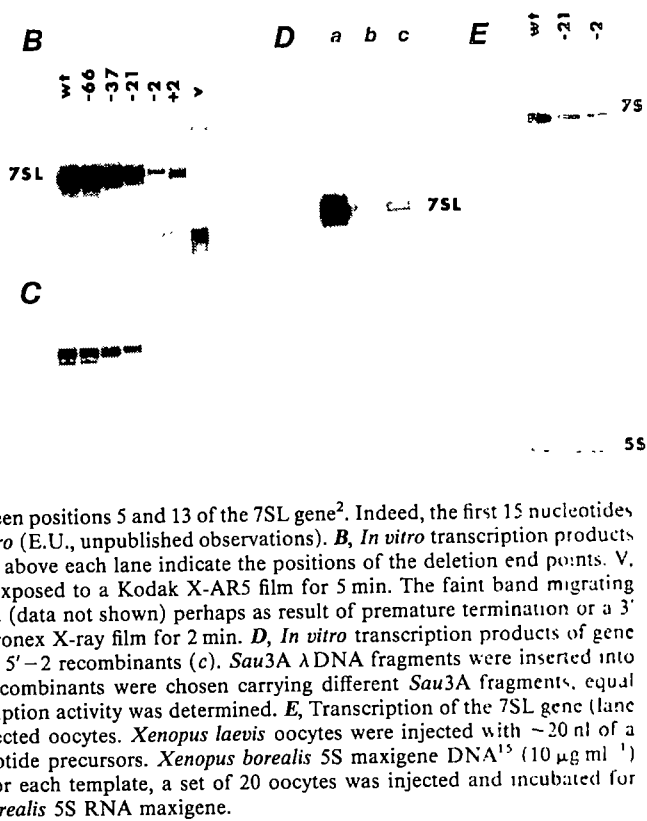

Fig. 2 A, Nucleotide sequences and transcription efficiencies of the 5' deletion derivatives of the 7SL gene 7L30.1 (wt). Progressive deletions of the 5'-flanking DNA of gene 7L30.1 were generated either by digestion with restriction enzymes or with *Bal31* nuclease. The 5' deletion derivatives are named according to the position of the deletion end point. Structures of the deleted templates were verified by DNA sequence analysis using the chemical degradation method³⁵. The 5'-37 recombinant was constructed by digestion of p7L30.1 with *Pst*I plus *Eco*RI, followed by insertion of the resulting fragment at the corresponding sites in pUC13 DNA. The other 5' deletions were inserted between the *Sma*I and *Eco*RI sites of the same plasmid vector. The beginning of the 7SL RNA coding sequence is underlined. Upper case letters: natural 5'-flanking DNA; lower case letters: pUC13 vector DNA. Arrowheads: transcription initiation sites mapped by T1 fingerprint and 5' end-group analysis. Solid bar: presumptive initiation sites; we did not determine the precise initiation sites of 5'-2 and 5'+2 RNAs, but their 5' ends mapped within the cluster of C residues abutting the 7SL coding sequence. Arrows below the wild-type sequence indicate a set of three 9-bp direct repeats. The transcription efficiencies represent both the highest and the lowest obtained using several different preparations of HeLa cell nuclear extract. Note that a sequence closely resembling the A block consensus sequence of transfer RNA promoters³⁶ is located between positions 5 and 13 of the 7SL gene². Indeed, the first 15 nucleotides upstream from the 7SL coding sequence are essential for expression *in vitro* (E.U., unpublished observations). **B**, *In vitro* transcription products of the 7SL gene 7L30.1 (wt) and of the 5' deletion derivatives. Numbers above each lane indicate the positions of the deletion end points. V, the products of transcription of pUC13 vector DNA. The wet gel was exposed to a Kodak X-AR5 film for 5 min. The faint band migrating faster than 7SL RNA is a 7SL transcript which is truncated at the 3' end (data not shown) perhaps as result of premature termination or a 3' exonuclease activity. **C**, As in **B** except that the gel was exposed to a Cronex X-ray film for 2 min. **D**, *In vitro* transcription products of gene 7L30.1 (a), the 5'-2 deletion mutant (b) and a pool of 13 independent 5'-2 recombinants (c). *Sau*3A λ DNA fragments were inserted into the *Bam*HI site at position -10 of the 5'-2 clone; 13 independent recombinants were chosen carrying different *Sau*3A fragments, equal amounts of the various DNAs were pooled, and their cumulative transcription activity was determined. **E**, Transcription of the 7SL gene (lane 30), the 5'-21 (lane 21) and the 5'-2 (lane 2) deletion mutants in injected oocytes. *Xenopus laevis* oocytes were injected with ~20 nl of a solution containing plasmid DNA (400 μ g ml⁻¹) and radioactive nucleotide precursors. *Xenopus borealis* 5S maxigene DNA¹⁵ (10 μ g ml⁻¹) was co-injected as an internal control for the efficiency of injection. For each template, a set of 20 oocytes was injected and incubated for 20-24 h at 20 °C. 5S indicates the products of transcription of the *X. borealis* 5S RNA maxigene.

DNA, was 10-50 times less active than the wild-type gene. The upstream vector sequences do not contain an inhibitor of transcription, because replacement of vector DNA by a random collection of bacteriophage λ DNA fragments had no effect (Fig. 2D). Second, a good proportion of the transcripts produced from these mutant 7SL genes were larger than 7SL RNA (Fig. 2C). As judged by T1 fingerprinting and 5'-end-group analysis, approximately 10% of the transcripts from deletion mutants 5'-21, 5'-2 and 5'+2 were initiated correctly, while the remainder had 5' ends mapping a few nucleotides upstream from the G residue at position 1 (see Fig. 2A; data not shown). The failure of these 7SL deletion mutants to accumulate significant levels of 7SL RNA must reflect a decrease in the efficiency of transcription, since pulse-chase experiments *in vitro* did not reveal any difference in the turnover rate of the 5'-2 RNA as compared with authentic 7SL RNA (data not shown).

To determine whether the efficiency of transcription depends on the distance between the 5'-flanking sequences and the 7SL coding region, we constructed a second set of mutant 7SL genes

with 9, 11 and 13 extra nucleotides inserted at position -6 of the 7L 5'-66 template (Fig. 3A). Relative to the parent template (Fig. 3B), these mutations caused a ~10-fold reduction in transcription activity, and led to aberrant initiation upstream, as assayed by primer extension (Fig. 3C). Further increases in the length of the linker DNA inserted at position -6 did not significantly change the pattern of initiation observed with mutant DL+13 (data not shown). We conclude that the sequences upstream from the 7SL gene, in conjunction with the internal control region, provide information for positioning the correct start site of transcription; moreover, optimal transcription requires that the distance of the upstream DNA from the internal promoter is not altered.

Finally, the 5'-flanking sequence of the 7SL gene increases the efficiency of transcription from the 7SL internal promoter *in vivo* as well as *in vitro*. After injection into the nucleus of *Xenopus* oocytes, the 5'-21 and 5'-2 mutant templates (Fig. 2E) were transcribed 5-10-fold less efficiently than the wild-type gene, even though this is a heterologous system. In addition, the 5'-21 and 5'-2 transcripts were longer than 7SL

Fig. 3 **A**, Nucleotide sequences of mutant 7SL genes *DL+9*, *DL+11* and *DL+13* and position of the initiation sites mapped by primer extension (▼). The linker sequences are underlined. The *DL+9* recombinant was constructed by inserting an *XhoI* linker at position -6 of 7L 5'-66 DNA, after digestion³⁷ with DNase I in the presence of Mn²⁺. *DL+11* and *DL+13* were obtained by filling the ends of *XhoI*-digested *DL+9* DNA with Klenow polymerase and deoxynucleotide triphosphates. **B**, Products of *in vitro* transcription of 7SL mutants *DL+9* (lane +9), *DL+11* (lane +11) and *DL+13* (lane +13) and of 7L 5'-66 (lane 0). **C**, Primer extension analysis of 7SL RNA and of *DL+9*, *DL+11* and *DL+13* RNAs synthesized *in vitro*. The following RNAs were used as templates: lane 1, endogenous RNAs after micrococcal nuclease digestion; lane 2, endogenous RNAs before micrococcal nuclease digestion; lane 0, 7SL RNA synthesized from 7L 5'-66 DNA; lane +9, *DL+9* RNAs; lane +11, *DL+11* RNAs; lane +13, *DL+13* RNAs. M, end-labelled *HpaII* fragments of pBR322 DNA.

Methods. The 5' ends of the transcripts were mapped by primer extension using an oligonucleotide complementary to positions 96-110 of 7SL RNA. The endogenous RNAs of the transcription extract³¹ gave two major extension products of 110 and 190 nt (lane 2); the 110-nt cDNA corresponds to 7SL RNA, while the origin of the longer product is unknown. The extract was therefore digested with micrococcal nuclease before transcription (lane 1) to remove these endogenous RNAs. Micrococcal nuclease (5,000 U ml⁻¹) was added to HeLa cell nuclear extract containing 1 mM CaCl₂ and the digestion was carried out for 15 min at 30 °C. Nuclease digestion was stopped by addition of 2 mM EGTA; transcription reactions contained 500 µM of each of the four ribonucleotide triphosphates. Nucleic acids were purified by phenol extraction and, after ethanol precipitation, annealed to a 10-fold molar excess of the 5'-end-labelled synthetic oligonucleotide. Reverse transcription was carried out as described by Hernandez and Keller³⁸. cDNA products were fractionated through a 6% polyacrylamide gel containing 7 M urea.

RNA and identical in structure to the corresponding transcripts synthesized *in vitro*.

Our results have evolutionary implications. *Alu* elements are thought to transpose to new chromosomal sites using an RNA polymerase III transcript as an intermediate^{13,14}. The 5' end of the transposed *Alu* information is therefore defined by the initiation site for transcription of the parental *Alu* element, and each newly transposed *Alu* element acquires a new 5'-flanking sequence. Deletions and substitutions of the 5'-flanking sequences in a variety of genes transcribed by RNA polymerase III genes are known to affect the accuracy of initiation¹⁵⁻¹⁷ and to modulate either positively¹⁸⁻²² or negatively²³⁻²⁵ the efficiency of transcription. We have shown here that alterations in the 5'-flanking DNA of the human 7SL gene markedly decrease the efficiency of transcription and lead to the appearance of heterogeneous start sites. We speculate that the 5'-flanking sequences of most newly inserted *Alu* elements are unlikely to be compatible with maximal transcription and that only a small subset of mammalian *Alu* family members account for most *Alu* transcription *in vivo*. This subset of *Alu* elements ('founder elements') would produce most of the transcripts that serve as intermediates for transposition to new chromosomal sites. Mutations occurring in these founder elements when the copy number of *Alu* sequences was low at the time of the mammalian radiation, would lead to the observed species-specific differences between mammalian *Alu* sequences²⁶⁻²⁹, as the copy number of *Alu* sequences increased in each species³⁰.

We thank Doug Black for the 7SL oligonucleotide, Manny Ares and Chang-Yee Yuo for teaching us how to inject oocytes and Manny Ares, Nouria Hernandez, Ellen Gottlieb and Chris Tschudi for the critical reading of the manuscript. E.U. was the recipient of a Grant-in-Aid from the Sigma Delta Epsilon, Graduate Women in Science, Inc. This work was supported by NIH grants GM 31073 and 31335.

Tailoring the pH dependence of enzyme catalysis using protein engineering

Paul G. Thomas, Alan J. Russell & Alan R. Fersht

Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK

One of the goals of protein engineering is to tailor the pH dependence of enzyme catalysis to optimize activity in industrial processes. Chemical modification studies have shown that the pH dependence of catalysis by serine proteases alters with changes in overall surface charge¹, which suggests that a possible general method of modifying pH dependence is to alter the electrostatic environment of the active site by protein engineering and so change the pK_a values of ionic catalytic groups. Electrostatic effects are of considerable importance in enzyme catalysis and are thought to play a major part in stabilizing charged transition states²⁻⁵. However, it is extremely difficult to calculate electrostatic effects in proteins because of the microheterogeneity of the dielectric constant. In the present study we show how the change of just one surface charge which is 14–15 Å from the active site of subtilisin has a significant effect on the pH dependence of the enzyme and that the magnitude of the effect changes with ionic strength in a manner qualitatively consistent with electrostatic theory. Such experiments should provide the basis for refining theoretical calculations of electrostatic effects in catalysis.

The subtilisins are a family of extracellular serine proteases (also known as alkaline proteases) produced by species of bacilli prior to sporulation⁶. His 64 at the active site of the enzyme acts as a general base during catalysis, accepting a proton from the nucleophilic residue Ser 221 as it forms a bond with the substrate carbonyl carbon. The enzyme is active at alkaline pH when His 64 is unprotonated, and catalytic activity varies with pH following the ionization of this residue. The mutation we have chosen for our investigation of the magnitudes of electrostatic effects is Asp→Ser 99 in subtilisin from *Bacillus amyloliquefaciens* (BPN' or Novo). Crystallographic data show that this surface aspartate is some 14–15 Å from the imidazole of His 64 (ref. 7). (Note that because of a sequencing error, there is an alanine at position 99 in the early crystallographic models. We built in an aspartate at this position using molecular graphics. The derived distances have been substantiated by a new refined structure (R. Bott, personal communication)—the His 64 C γ -Asp C γ distance is 13 Å in the refined map, the same as in our modelling.) Asp 99 is not conserved in highly homologous subtilisins from other organisms: there is a serine at this position in the subtilisins from *Bacillus subtilis* DY⁸ and *Bacillus licheniformis*⁹ and threonine in subtilisins from *B. subtilis*¹⁰ and *Bacillus amylosacchariticus*¹¹. It is thus expected *a priori* that the mutation Asp→Ser 99 should not have a significant effect on either the structure or catalytic properties of the enzyme other than by electrostatic effects. Removal of the negative charge of Asp 99 should destabilize the low-pH, positively charged form of His 64 and so lower its pK_a from the normal value of 7 by an unknown amount.

To test the predictions and quantify the effects, we have cloned the structural gene encoding subtilisin BPN' from *B. amyloliquefaciens* in the vector pUB110 (refs 12, 13). The structure of pPT30, which harbours the subtilisin gene on a 3.4-kilobase (kb) *EcoRI* fragment, is shown in Fig. 1a; its construction will be described elsewhere. The DNA sequence of the structural gene was determined by dideoxy methods¹⁴ using a series of primers (J. Brannigan, unpublished data) and is identical to that published elsewhere^{15,16}. Wild-type subtilisin BPN' is expressed and secreted at high levels by *B. subtilis* DB104 transformed with pPT30 (Fig. 1b). The strain DB104, given by Dr R. Doi, is deficient in extracellular alkaline and neutral proteases¹⁷. Subtilisin(Asp→Ser 99), prepared by oligodeoxynucleotide

Fig. 1 a, Restriction map of the subtilisin expression vector pPT30. The subtilisin gene is contained within a 3.4-kb *EcoRI* fragment (solid block). Sequences derived from pUB110 (4.5 kb) are delineated by the arrowheads. b, Secreted subtilisin gives a characteristic clear halo around colonies of *B. subtilis* DB104 harbouring pPT30 after overnight selection on L-agar containing 1% skimmed milk plus 25 $\mu\text{g ml}^{-1}$ kanamycin.

Methods. For mutagenesis, the gene was recloned in M13mp9. M13aprWT was constructed such that the coding strand of the subtilisin gene was ligated to the (+) strand of the viral DNA. M13aprWT was propagated in *Escherichia coli* TG2, a *recA*⁻ derivative of JM101 (M. Biggin and T. Gibson, unpublished results) to overcome problems of DNA instability encountered when JM101 was the host. The synthetic primer (5'CGGAACCGCTAG-CACG3') contained a double mismatch with the wild-type gene (indicated by asterisks) and was designed to introduce an acceptable Ser codon at position 99. Oligodeoxynucleotide-directed mutagenesis was performed as described elsewhere^{20,21}, except that the mismatch repair-deficient strain BMH71-18mutL²² was the recipient in transformations. TG2 provided the lawn to isolate phage from the mutator background. Hybridization screening using the mutagenic primer as a probe showed that 20% of the plaques contained mutant phage. The mutation was confirmed by DNA sequencing after plaque purification. Subtilisin(Asp→Ser 99) was expressed in DB104 on transformation of competent cells²³ with a plasmid constructed by ligating the mutant gene isolated from replicative form DNA into pUB110 in the same orientation as pPT30. Wild-type and mutant enzymes were purified from 36-h culture supernatants grown in L-broth containing kanamycin (25 $\mu\text{g ml}^{-1}$) and glucose (0.2%). The supernatant was concentrated using a Pellicon membrane filter (PTGC00005, Millipore) before dialysis against 0.01 M phosphate buffer pH 6.2 and purification on a CM-52 cellulose column as described elsewhere (ref. 24).

mutagenesis (Fig. 1), is also expressed at similar high levels in DB104.

The activity of subtilisin(Asp→Ser 99) on the synthetic substrate succinyl-L-alanyl-L-alanyl-L-prolyl-L-phenylalanyl *p*-nitroanilide is similar to that of wild-type enzyme at 25 °C in 0.1 M Tris-HCl buffer, pH 8.6: k_{cat} (the catalytic rate constant) for the wild-type enzyme is 57 s⁻¹ and K_m (Michaelis constant) is 0.15 mM, while the corresponding values for the mutants enzyme are 45 s⁻¹ and 0.13 mM. The wild-type enzyme has identical activity to that produced from an independently cloned gene (ref. 15 and D. A. Estell and J. A. Wells, personal communication). The pK_a values of the active sites of the free enzymes were determined by kinetics from the pH dependence of k_{cat}/K_m (Fig. 2, Table 1). At ionic strength 0.1, His 64 in the wild-type enzyme has a pK_a of 7.17 ± 0.02 ; this is decreased to a value of 6.88 ± 0.03 in the mutant, a shift of 0.29 ± 0.04 units. k_{cat}/K_m is decreased by 20% on mutation. Thus, Asp 99 affects both the ionization constant of the active site and also the charged transition state of the reaction.

As a control, it is important to examine the effect of ionic strength on the electrostatic interactions. The presence of high concentrations of ions should mask electrostatic interactions. At high ionic strengths, the observed pK_a s should tend to their intrinsic values in the absence of surface charge. According to the classical Debye-Hückel theory and the Poisson-Boltzmann

Fig. 2 pH dependence of k_{cat}/K_m for the hydrolysis of succinyl-L-alanyl-L-alanyl-L-prolyl-L-phenylalanyl *p*-nitroanilide by wild-type (solid symbols) and mutant Asp→Ser 99 (open symbols) subtilisin at 25 °C, ionic strength 0.1 (a) or 1.0 (b). Phosphate (circles) and Tris-HCl (squares) buffers of ionic strength 0.1 were used and the ionic strength adjusted by the addition of KCl. The reaction was initiated by adding 15 μl of enzyme (13 μM in 0.01 M phosphate buffer, pH 6.2) to 2 ml of buffered substrate (0.02 mM, $\ll K_m$) in a cuvette maintained at 25 °C in a Gilford 2600 spectrophotometer. The increase in absorbance at 412 nm on the release of *p*-nitroaniline was monitored and found to follow, with high accuracy, simple first-order kinetics. The value of k_{cat}/K_m at each pH value was determined from the first-order plots exactly as described for the hydrolysis of acetyl-L-tyrosine *p*-acetylanilide by chymotrypsin²⁵. The low concentration of substrate used in this method avoids product inhibition. The concentration of each enzyme was determined by active-site titration with *N*-trans-cinnamoyl imidazole²⁶. Wild-type enzyme was found to be 91% active and the mutant 96% active compared with concentrations measured by A_{280} ($E_{0.1\%} = 1.17$). Control experiments showed that the rate of reaction in Tris-HCl buffers was 15% lower than in phosphate buffers. The data for experiments in the presence of Tris-HCl have been corrected for this, but these data were not used in the analysis. The data for the experiments in phosphate buffer were fitted to a theoretical single ionization curve by nonlinear regression (R. J. Leatherbarrow, unpublished). The derived pK_a values are listed in Table 1.

equation, the electrostatic interaction between two ions separated by a distance r is reduced by a factor of $\exp(-r/r_D)$ where r_D , the Debye length, is inversely proportional to the square root of the ionic strength. At ionic strength 1.0, r_D is 3.1 Å and at ionic strength 0.1 it is 9.8 Å. Although the theory is only approximate at high ionic strength, electrostatic effects should be highly masked over a distance of 14–15 Å at ionic strength 1.0. Accordingly, we found (Table 1) that at this ionic strength, both the pK_a values of the active site and the catalytic activities of the wild-type and mutant enzymes converge ($pK_a = 7.11 \pm 0.02$ and 7.09 ± 0.02 ; $k_{\text{cat}}/K_m = (45 \pm 0.6) \times 10^4$ and $(42 \pm 1) \times 10^4 \text{ s}^{-1} \text{ M}^{-1}$ respectively). Thus, the mutation Asp→Ser 99 has essentially no effect on the catalytic properties of the enzyme when electrostatic effects are masked.

Table 1 The pH dependence of hydrolysis by wild-type and mutant subtilisin

Enzyme	pK_a of active site (from kinetics)	Limiting value of k_{cat}/K_m at high pH ($\text{s}^{-1} \text{ M}^{-1} \times 10^{-4}$)
Ionic strength 0.1		
Wild type	7.17 ± 0.02	48.9 ± 0.7
Asp→Ser 99	6.88 ± 0.03	40.8 ± 0.9
Ionic strength 1.0		
Wild type	7.11 ± 0.02	44.8 ± 0.6
Asp→Ser 99	7.09 ± 0.02	41.6 ± 0.9

The pK_a values were obtained from the pH dependence of k_{cat}/K_m on the hydrolysis of succinyl-L-alanyl-L-alanyl-L-prolyl-L-phenylalanyl *p*-nitroanilide at 25 °C. The pH dependence of k_{cat}/K_m gives the pK_a values of the free enzyme and free substrate. In this case, the only ionizing group on the substrate is the succinyl group and its pK_a is below the range of this study. Artefacts which often obscure the interpretation of the pH dependence of k_{cat} and K_m individually usually do not affect the pH dependence of k_{cat}/K_m (ref. 18). The pK_a of the wild-type enzyme is in excellent agreement with that derived from the hydrolysis of ester substrates in identical conditions (7.15 at ionic strength 0.1; ref. 19). Values are given \pm s.e.

We have shown that modification of a single charge in the vicinity of the active site of an enzyme can have a significant effect on the pH dependence of the catalytic reaction. Such effects should be larger for charges which are closer to ionic catalytic residues in the enzyme or closer to charges which develop in the transition states. Electrostatic effects will be more pronounced if multiple charges are engineered. It should, therefore, be possible to engineer large effects on both the pH dependence and catalytic rate constants by modifying the surface charge.

This work was supported by the SERC of the UK. We thank Mr J. Brannigan for providing sequencing primers and determining the DNA sequence of the wild-type gene. We also thank Dr Bott for pre-publication data on the distance between His 64 and Asp 99, and Dr J. A. Wells for the sequence of the cloned subtilisin gene prior to publication.

Loss of genes on the short arm of chromosome 11 in bladder cancer

Eric R. Fearon*, Andrew P. Feinberg*†, Stanley H. Hamilton‡ & Bert Vogelstein*

* The Oncology Center, † Department of Medicine, and ‡ Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA

Recent studies have shown that normal cellular sequences on chromosome 13 are lost during the development of retinoblastomas¹ and that sequences on chromosome 11 are similarly lost during the development of Wilms' kidney tumours²⁻⁵ and embryonal tumours⁶. Cells from these tumours have been found to contain either the paternal or maternal copies of loci on the affected chromosome, but not both. Thus, the somatic loss of heterozygosity for sequences on chromosome 13 or 11 is hypothesized to result in homozygosity for a recessive mutant allele on these chromosomes¹, and in this way the chromosomal loss may contribute to the development of these tumours. We sought to investigate whether similar losses of heterozygosity for chromosome 11 sequences occurred in a common adult tumour. We chose to analyse bladder cancers, since such cancers are common in the adult population and are derived from urogenital tissue, as are Wilms' tumours. We examined constitutional and tumour genotypes at loci on the short arm of chromosome 11 (11p) in 12 patients with transitional cell carcinomas. In five tumours, we observed the somatic loss of genes on 11p resulting in homozygosity or hemizygosity of the non-deleted alleles in the tumour cells. Our results show that the frequency of loss of 11p sequences in bladder cancer approaches that seen in Wilms' tumour (42% compared with 55%)⁷, and suggest that recessive genetic changes involving sequences on 11p may contribute to the development of bladder neoplasms.

The patients studied were 50-85 years old and all had histologically confirmed transitional cell carcinoma (11 of the bladder, 1 of the ureter). All tumour tissues were obtained before any chemotherapy or radiotherapy, and the histological stage and grade of each patient's tumour is indicated in Table 1. DNA of high relative molecular mass was isolated from tumour and normal tissues (either normal bladder mucosa or peripheral leukocytes). To detect the somatic loss of chromosome 11p sequences in the tumours, we exploited DNA polymorphisms on chromosome 11. DNA polymorphisms are normal variations in DNA sequence that occur in the human population and may be used to distinguish the maternal and paternal copies of a gene. The variations can be detected by Southern blotting of

the patient's DNA using a cloned copy of the gene of interest as a probe. Comparison of DNA from normal and tumour tissue can reveal instances where either the paternal or maternal copy of a gene was lost during tumorigenesis.

Two genes on 11p that display DNA polymorphisms are *c-Ha-ras-1* and the insulin gene. *c-Ha-ras-1*, the human homologue of the transforming gene of the Harvey murine sarcoma virus, has been localized⁸ near the distal end of 11p. It displays a length polymorphism due to variations in the number of reiterations of a small tandemly repeated sequence located approximately 1.5 kilobases (kb) 3' to its coding region⁹. Similarly, the insulin gene has been assigned¹⁰ to 11p and it contains an insertion of variable length located approximately 1 kb 5' from the transcriptional start site of the gene¹¹. Figure 1 shows representative Southern blots of DNA from normal and tumour tissues probed with *c-Ha-ras-1* or insulin. Analysis of normal bladder DNA from patient A1 revealed two *c-Ha-ras-1* alleles (denoted 1 and 2 in Fig. 2). No loss of either allele was detected in tumour cells from this patient. Normal tissue from patient A2 was also polymorphic for the *c-Ha-ras-1* gene. However, in this patient's tumour tissue allele 2 was absent (see Fig. 1, lanes A2). Patient D was not heterozygous at the *c-Ha-ras-1* locus, but did display polymorphism at the insulin locus. His normal tissue revealed two insulin alleles (1 and 2 in Fig. 1, lanes D). DNA from his tumour tissue, however, showed significant loss of the hybridization signal from allele 1. Normal tissue from patients M, S2 and T was heterozygous at *c-Ha-ras-1*; in their tumour tissues, these patients had a marked reduction in the intensity of alleles 1, 2 and 1, respectively (see Fig. 1). All 12 patients were heterozygous at either the *c-Ha-ras-1* or the insulin locus. The six patients not shown in Fig. 1 exhibited no loss of 11p alleles in their tumour tissues (see Table 1). There was no apparent correlation between tumour stage or histological grade and the loss of 11p alleles.

To determine whether the losses of 11p alleles in tumour tissue were associated with duplications of the retained alleles, as was previously demonstrated in Wilms' tumours²⁻⁵ and embryonal tumours⁶, we quantified the hybridization signals seen in Fig. 1. At least one Southern blot filter from each of the patients was rehybridized with one or more DNA probes derived from sequences present on chromosomes other than 11. Autoradiographs of these blots were scanned with a densitometer and analysed to determine the ratios of hybridization of restriction fragments obtained from the normal and tumour DNA. In Fig. 2, it can be seen that the hybridization signal of the remaining 11p alleles in patients A2 and D is of approximately double intensity in the tumour cells, and is unchanged in patients M, S2 and T. Thus, the losses of 11p alleles in tumour cells of patients A2 and D were associated

Fig. 1 Representative Southern hybridizations of 11p gene probes to normal tissue (N) and transitional cell carcinoma (C) DNA. Patient designations are shown above the blots, and the numbers shown on the left indicate the polymorphic alleles (numbers correspond to the text and Table 1). Blots from patients A1, A2, M, S2 and T are *MspI* digests of DNA hybridized to the *c-Ha-ras-1* gene probe. DNA from patient D (and sample D') was digested with *HinfI* and hybridized to the insulin gene probe. Note the preservation of heterozygosity at the *c-Ha-ras-1* locus in tumour DNA of patient A1, while tumour DNA from patients A2, D, M, S2 and T reveal loss or marked reduction in the intensity of one allele. In addition, note the increased intensity of the retained allele in patients A2 and D. D' represents DNA extracted from frozen sections of patient D as described in the text.

from frozen sections of patient D as described in the text.

Methods. DNA of high relative molecular mass was prepared from bladder tumour biopsies and either normal bladder mucosa (patients A1, A2, D, M) or peripheral leukocytes (patients S2, T). The tissues were minced and digested overnight in 1% SDS and proteinase K (0.5 µg ml⁻¹) at 48 °C, and DNA was extracted with phenol and chloroform as described elsewhere¹². DNA concentrations were determined by a diphenylamine assay²¹. Approximately 1 µg of DNA was digested with each restriction enzyme, and the resulting DNA fragments were separated by electrophoresis through agarose gels and transferred to nitrocellulose filters^{22,23}. Gene fragments used as probes were: (1) a 1.0-kb *MspI* *c-Ha-ras-1* genomic fragment containing the polymorphic 3' flanking region²⁴; and (2) a 1.3-kb *PvuII* fragment from the recombinant plasmid hINS 5', containing the polymorphic sequences 5' to the insulin gene²⁵. The gene probe fragments were separated by electrophoresis and oligolabelled directly in agarose to a specific activity of >10⁹ d.p.m. µg⁻¹ (refs 26, 27). Southern hybridization²², post-hybridization washing²³ and autoradiography²⁹ were performed as described previously.

Allelic assignments were determined by Southern hybridizations to 11p gene probes and to probes from chromosomes other than 11p. For each probe, alleles are named with '1' as the larger restriction fragment and '2' or '3' as smaller fragments. '—' Indicates that normal and tumour samples were not analysed with a given probe, due to insufficient amounts of DNA. Chromosomes and the polymorphic probes used to mark these chromosomes are indicated at the top of the table. The clinical stage (T) and histopathological grade (t) of each tumour examined are indicated³². Southern hybridizations as described in the legend to Fig. 1 were performed with the following DNA probes: (1) antithrombin III (ATIII) (chromosome 1q, *Pst*I digest)³³; (2) carbamyl phosphate synthetase (CPSI) (chromosome 2p, *Bgl*II digest)^{13,33}; (3) DOSL C9 (chromosome 3, *Msp*I digest)³⁴; (4) collagen $\alpha 1$ (II) (chromosome 12q, *Hind*III digest)³⁵; (5) p7F12, p9D11, p9A7 (chromosome 13q, *Msp*I digests)³⁰; (6) pAW101 (chromosome 14q, *Eco*RI digest)¹⁴; (7) DOSL C3 (chromosome 15, *Msp*I digest)³⁴; (8) growth hormone (GH) (chromosome 17, *Msp*I digest)³⁶; (9) DOSL C6 (chromosome 18, *Taq*I digest)³⁴; and DOSL C2 (chromosome 20, *Msp*I digest)³⁴. Allele copy number was determined by densitometric analysis.

with duplications of the retained alleles, while a simple loss of 11p genes occurred in tumour cells of patients M, S2 and T, resulting in hemizyosity for 11p sequences.

Densitometric analysis also confirmed the marked reduction in intensity of one allele in each of the patients analysed in Figs 1 and 2. The hybridization signal corresponding to the deleted allele was diminished by 90%, 80%, 90%, 65% and 90% in patients A2, D, M, S2 and T, respectively, when tumour tissue was compared with normal tissue. Complete loss of the signal for the deleted allele was not observed. Two possible explanations for the remaining hybridization signal in the DNA from the tumour specimen were: (1) all tumour cells had lost an allele, but contaminating non-tumour cells were present within the tumour; or (2) the majority, but not all, of the tumour cells had lost an allele. In support of the first possibility, histological sections of tumour specimens from these patients revealed numbers of stromal cells roughly consistent with the signal remaining in the band corresponding to the deleted allele. However, possible cellular heterogeneity within the tumours created difficulty in ascertaining that the piece of tumour tissue used to prepare DNA had the same proportion of non-tumour and tumour cells as that examined for histopathological diagnosis. To address this potential problem, we extracted DNA from tissue sections in which the relative DNA contribution of tumour and non-tumour cells could be precisely determined. A piece of the tumour from patient D was frozen in OCT compound and 100 serial 6- μ m sections were cut with a cryostat. Sections 1, 51 and 99 were stained with haematoxylin and eosin for histological analysis and the remainder of the sections were used to prepare DNA using a technique described recently¹². The Southern blot obtained with the DNA from these sections is shown in Fig. 1, lanes D'. The result is quite similar to that obtained with the DNA isolated from a large piece of this tumour (Fig. 1, lanes D). Densitometry of the autoradiograph showed that the signal corresponding to the deleted allele was diminished by 83% when the DNA from the tumour sections was compared with

normal tissue from the same patient. Histological analysis revealed that 67% \pm 15% of the cells within these sections (3,800 cells in 26 fields examined) were tumour cells. Section 100 was stained with Feulgen, and microdensitometry was performed using a Leitz DAD video analysis system. This analysis revealed that the normal cells within the tumour had a relative DNA content of 1.0 \pm 0.15 while the tumour cells had a relative DNA content of 1.29 \pm 0.33. Hence, we expected that 86% (1.29 \times 67%) of the DNA extracted from these sections would be derived from tumour cells, and 14% derived from stromal cells within the tumour tissue. Comparison of the results of histological analysis and Southern blot analysis suggests that the residual hybridization of allele 1 in the tumour specimen from patient D was largely derived from contaminating stromal cells.

To obtain evidence that the changes we observed were specific to 11p and not simply widespread random alterations, we also examined DNA markers on chromosomes 1-3, 12-15, 17, 18 and 20. These data are summarized in Table 1. Interestingly, some changes were noted when genes from normal and tumour DNAs were compared on these chromosomes, but the incidence of these changes was less frequent than those seen on 11p. For example, we detected the loss of one carbamyl phosphate synthetase I allele (chromosome 2p)¹³ in each of the tumours from patients A2 and D (Table 1), and the loss of one pAW101 allele (chromosome 14q)¹⁴ in patient M. In addition, while reduction to homozygosity for chromosome 13 markers occurs in 60% of retinoblastomas¹, we did not observe the loss of any chromosome 13 markers in bladder tumours. Tumour tissues from patients M and T did exhibit a duplication of sequences on one chromosome 13 homologue, resulting in triploidy for chromosome 13 sequences (Table 1). Similarly, comparison of DNA obtained from tumour tissues of patients A1, D and P with DNA from their normal tissues showed hybridization intensities consistent with triploidy for chromosome 20 or chromosome 15 sequences in the tumour tissues. No other qualitative or quantitative chromosomal changes were detected in the other chromosomes

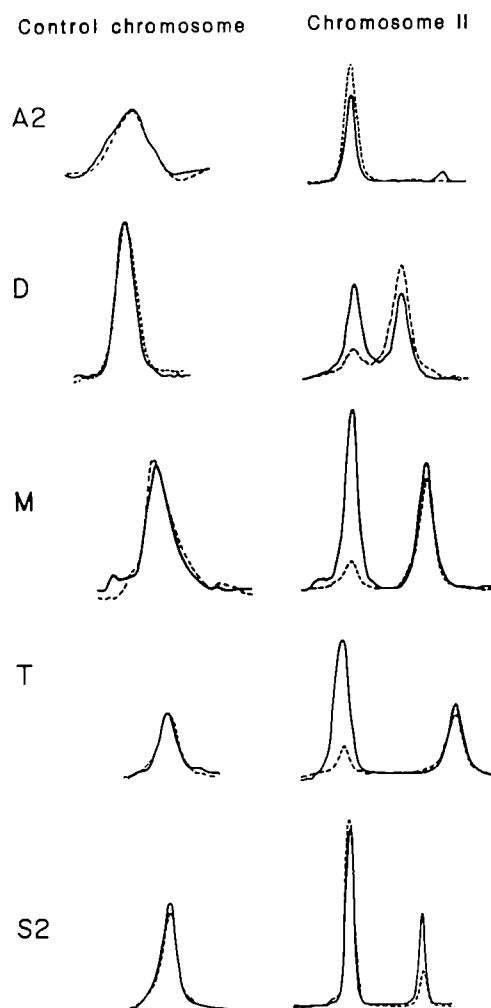

Fig. 2 Densitometric analyses of Southern hybridizations with 11p gene probes and of rehybridizations with non-chromosome 11 genes (control chromosome). Solid lines, normal lanes; broken lines, tumour lanes. Patient designations are indicated to the left. **Methods.** Southern blots (from Fig. 1) were freed of probe in alkali and rehybridized with control genes: (1) p9A7, a recombinant plasmid containing 0.95 kb of sequences derived from chromosome 13q³⁰ (patients A2, D and M; allele 2 was used for comparisons between the normal and tumour tissues in all three patients); or (2) pEP2, a recombinant plasmid containing coding sequences from the ATIII gene on chromosome 1q³¹ (patients S2 and T). Grain density was quantified using a Clifford Densicom model 445 densitometer. After normalizing the control scans for DNA loading, the 11p gene blots were re-scanned to produce the tracings shown.

examined (see Table 1). Hence, while loss of 11p sequences is certainly not the only genetic event that occurs in bladder cancer, our data would argue that such loss is relatively frequent in this cancer, and may be one of the important steps involved in development of this tumour.

We were unable to perform karyotypic analyses of the tumours studied. However, previous karyotypic analyses^{15,16} of transitional cell bladder carcinomas have revealed alterations of chromosome 1, 5, 8, 9, 11 and 13. Significantly, chromosomal losses involving 11p were seen in a subfraction of tumour cells from 3 of 9 patients in one study¹⁵ and at least 3 of 10 patients in another¹⁶. We observed a higher incidence of 11p losses than that revealed by karyotypic analysis. In addition, our results indicated that loss of 11p sequences occurred in the majority of the tumour cells from 5 of 12 patients. Thus the situation with bladder tumours is similar to that seen in Wilms' tumours, wherein analysis of DNA polymorphisms reveals a higher incidence of loss of 11p sequences than usually seen karyotypi-

cally¹⁷. These differences between the two analyses may be attributed to: (1) the difficulties inherent in cytogenetic studies of complex karyotypes from solid tumour specimens; (2) karyotypic analysis may be biased towards cells with the highest mitotic indices, while DNA polymorphism analysis represents an averaging of all cells within the tumour specimen; and (3) abnormal chromosome segregation which produces loss and reduplication events without gross loss of chromosomal material (such as that likely to have occurred in patients A2 and D) will not be detected karyotypically.

The chromosome 11 losses we observed were probably important for some stage of tumorigenesis in the five cases in which they occurred. This conclusion is strongly supported by our observation that the chromosomal loss, when observed, appeared to be present in nearly all cells of the tumour specimens (see Fig. 2). Hence, the losses did not simply occur in a small subclone of the tumour cell population; rather, the clone that lost 11p sequences apparently had a selective advantage sufficient to allow it to outgrow virtually all other cells.

There are at least two possible explanations for the growth advantage associated with loss of 11p sequences. First, it is possible that a normal cellular constraint of growth is present on chromosome 11p, and that the loss of this suppressor locus leads to activation of a normally repressed class of genes¹⁸. This mechanism does not seem to involve a simple dosage phenomenon. Bladder tumours from patients A2 and D and all of the Wilms' tumours in previous studies had a normal dosage of chromosome 11p arms, even though this diploid dosage was due to the loss of one chromosome 11p and the duplication of its homologue. Hence, for this explanation to be correct, one must postulate that two events had occurred in these cases: an inactivation of one chromosome 11p suppressor locus (by mutation, for example) followed by a loss of the chromosome 11p containing the normal suppressor locus, sometimes accompanied by the duplication of the abnormal 11p^{1,19}.

An alternative explanation for our results is that the events involving loss of 11p are simply correlated with another event that results in loss of growth control. In this model, the loss of 11p would itself have no intrinsic effect on the development of the tumour. For example, if a cell was prone to aneuploidy and chromosome 11 losses were not lethal to the cell, then some cells with a loss of chromosome 11 might also contain other alterations that could impart a growth advantage. This cell could then proliferate to produce a tumour with a clonal loss or loss and reduplication of 11p sequences. The fact that loss of 11p is only noted in 40–60% of bladder cancers and Wilms' tumours is consistent with this hypothesis.

In this context, however, examination of other tumours by molecular hybridization techniques does not reveal frequent loss of 11p. Of eight retinoblastomas studied for loss of 11p sequences, none showed loss of 11p^{1,20}. In addition, of 15 colon tumours examined, loss of 11p sequences was seen in only one tumour (E.R.F. and B.V., unpublished observations). Thus, loss of chromosome 11 sequences occurs frequently, and relatively specifically, in transitional cell carcinomas, Wilms' tumours, and other embryonal tumours. Its role in tumorigenesis will remain speculative, however, until the advent of studies which reveal the molecular effect of such loss.

We thank Dr Gunter F. Bahr (Armed Forces Institute of Pathology) for microdensitometry analysis, Dr Michael Droller for providing the tissues used in this study and Dr Susan Goelz for critical discussions. We are also grateful to the following investigators for DNA probes: Dr R. Weinberg for c-Ha-ras-1; Dr P. Rotwein for insulin; Dr P. O'Connell and Dr R. White for chromosome 13 sequences and DOSLC 2, 3, 6 and 9; Dr C. Prochownik for antithrombin III; Dr W. O'Brien for carbamyl phosphate synthetase I; Dr C. Francomano and A. Nunez for collagen 1(II); Dr S. Orkin for pAW101; and Dr P. Seeburg for growth hormone. We also thank Sandy Smith for typing the manuscript. This work was supported by the Clayton Fund, the Hartford Foundation (A.P.F.), training grant GM 07309 (E.R.F.), and NIH grant CA35494.

Although cystic fibrosis (CF) is among the most common inherited diseases in Caucasian populations¹, the basic biochemical defect is not yet known. CF is inherited as an autosomal recessive trait apparently due to mutations in a single gene²⁻⁴, whence the efforts made to identify the genetic locus responsible by linkage studies. Two markers have recently been identified that are genetically linked to CF: one is a genetic variation in serum level of activity of the enzyme paraoxonase⁵, and the other is a restriction fragment length polymorphism (RFLP) identified with a randomly isolated DNA probe⁴. We report here that the genetic locus DOCRI-917 defined by the cloned DNA probe is located on chromosome 7.

The polymorphic locus DOCRI-917 is detected with the probe LAM4-917, a phage clone from the genomic library of Lawn *et al.*⁶ which is one of a set of probes identified by a random screening procedure for RFLPs⁷. It is a 17-kilobase (kb) single-copy human genomic DNA sequence polymorphic both at a *HindIII* site and a *HincII* site in Southern blot hybridizations. The probe is frequently informative in inheritance studies, having a polymorphism information content⁸ of 0.57.

The structure and inheritance of the locus are described by Tsui *et al.*⁴.

The marker locus DOCRI-917 was identified by DNA hybridization in rodent-human hybrid cell lines containing different human chromosome complements⁹. Hybridization of the probe to DNA from 17 hamster-human hybrids, 8 mouse-human hybrids and the parental human and rodent cell lines is shown in Fig. 1. As expected from the restriction map of the DOCRI-917 locus⁴, four fragments (8.9, 5.8, 5.0 and 3.6 kb) are detected in all lanes with complementary genomic sequences. (Restriction fragment length polymorphism at the DOCRI-917 locus is not observed with *EcoRI*.) The probe does not cross-hybridize with mouse or hamster sequences (lanes CH and M).

Comparison of the LAM4-917 hybridization results with the chromosome content of the 25 cell lines indicates that the DOCRI-917 locus is situated on chromosome 7. Probe hybridization conforms to the expected pattern of a chromosome 7 locus in every line, and shows multiple discordances with all other chromosomes (Table 1). In one cell line (CH13) that scored positive with the LAM4-917 probe, chromosome 7 was present at an earlier passage but was no longer detectable by karyotype analysis or by assay of the β -glucuronidase isozyme marker GUSB¹⁰. At least some chromosome 7 sequences were present, however, as shown by hybridization of CH13 DNA with a complementary DNA clone of the T-cell receptor β -chain gene¹¹, located on chromosome 7 (q3) (refs 12-15). As shown in Table 1, the hybridization results of LAM4-917 to all 25 lines were identical to those obtained with the T-cell receptor β -chain probe.

All chromosomes except chromosome 7 are excluded because they are present in one or more of the cell line DNAs not hybridizing to LAM4-917. It is particularly important to note that chromosome 2, even though the number of discordances is low, is excluded as the location of DOCRI-917 by the absence of hybridization of the probe in the line CH8. Chromosome 2 was detected in karyotype analysis of CH8 metaphase cells, the cells were positive for the chromosome 2 isoenzymes MDH1 and IDH1¹⁶, and hybridization to a DNA probe from chromosome 2 (D2S1¹⁷) is clearly detected in the same CH8 DNA sample. Exclusion of DOCRI-917 from the X and Y chromosomes was also confirmed by hybridization to a set of cell lines with sex chromosome aneuploidies (results not shown).

Because of its established genetic linkage to DOCRI-917, we conclude that the cystic fibrosis locus is also situated on chromosome 7. Determination of the location of the cystic fibrosis gene is an important step in identifying the primary genetic defect responsible for the disease. Any hypothesis that a particular genetic function is the primary lesion must satisfy the criterion of mapping to the same site as the cystic fibrosis trait. With the discovery of linkage between CF and the genetic markers PON⁵ and DOCRI-917⁴, the location of the disease gene is restricted to the 1% of the genome surrounding these markers. By chromosomal localization of DOCRI-917, that region is now mapped to chromosome 7. More specific localization of DOCRI-917 on chromosome 7 will be possible by testing other hybrid cell lines containing partial deletions of chromosome 7, *in situ* hybridization to metaphase chromosomes, and linkage mapping with other chromosome 7 markers. The observation that the DOCRI-917 locus is present in cell line CH13, which appears to retain only a part of chromosome 7 lacking GUSB (cen \rightarrow q22) (ref. 18) but retaining the T-cell receptor β -chain gene TCRB on 7q3 is consistent with a location on 7q, but other explanations of this result are possible. For example, more than one segment of chromosome 7 might have segregated with this line, or the DNA hybridization may simply be more sensitive than the other methods used to detect chromosome 7.

Population studies have supported the hypothesis that mutations in a single autosomal gene are responsible for CF^{2,3}. In addition, the observation of only 15% recombination between CF and the marker DOCRI-917 in 39 families indicates that the disease is attributable to mutations at the site we have identified on chromosome 7 in the vast majority of these families⁴. At

Fig. 1 Autoradiogram of hybridization of LAM4-917 to DNA of 25 somatic cell hybrids. Genomic DNA prepared from each hybrid cell line was digested with *Eco*RI, separated and transferred to DBM-filters¹⁹. DNA of the phage clone LAM4-917 was radioactively labelled with ³²P by nick-translation to a specific activity of 2×10^8 d.p.m. μg^{-1} . Hybridization was carried out for 20 h at 42 °C in 50% formamide, 0.6 M NaCl, 0.05 M Tris-HCl pH 7.6, 0.1% sodium pyrophosphate, 0.1% SDS, 0.04% Ficoll, 0.04% polyvinylpyrrolidone, 0.04% bovine serum albumin, 5% dextran sulphate, and 250 $\mu\text{g ml}^{-1}$ sonicated, denatured salmon sperm DNA. The filters were washed in $2 \times \text{SSC}$ at 20 °C for 15 min and twice at 65 °C for 15 min, in $0.2 \times \text{SSC}$, 0.2% SDS at 65 °C for 40 min, and finally in $0.1 \times \text{SSC}$, 0.1% SDS at 65 °C for 40 min. The filters were exposed to Kodak XAR-5 film with intensifying screens (Dupont Cronex Lightning Plus) at -70 °C. The lane numbers (1-25) correspond to the hybrid cell lines listed in Table 1. Lanes 1-17 are hamster-human hybrids, and lanes 18-25 are mouse-human hybrids. A-E are the human parental cell lines, CH is the chinese hamster cell line V79.4, and M is the mouse line C11DA.

Chromosomal content of hybrid cell lines was determined by cytogenetic and isoenzyme analysis. The panel of hybrid cell lines was generated and characterized by Nguyen Van Cong, Dominique Weil and Catherine Finaz, Unité de Recherches de Génétique Médicale, INSERM U12, Paris, France, and is described elsewhere⁹. Symbols: +, chromosome detected in more than 30% of cells; -, chromosome not detected; /, chromosome detected in less than 30% of cells, not scored for mapping. Three of the human parental cell lines contained reciprocal chromosomal translocations^{20,21} retained by some hybrids: Xq/2q (Xqter → p22:2q32 → 2qter), Xp/5q (Xpter → q21:5q11 → qter), and 5p/Xq (5pter → q11:Xq21 → qter). Hybridization results for DOCRI-917 are from the autoradiogram in Fig. 1. The TCRB gene is detected by hybridization with the T-cell receptor β -chain probe¹¹ with the same cellular DNA samples. * Possible chromosome rearrangement, see text.

present, we cannot exclude the possibility that mutations in genes not linked to DOCRI-917 and PON are responsible for CF in a small percentage of families.

The localization of DOCRI-917 to chromosome 7 greatly facilitates the identification of other RFLP markers linked to CF. Polymorphic probes already assigned to chromosome 7 can be tested for linkage to CF, and collection of additional RFLP markers for this purpose can be accelerated by drawing probes from chromosome 7-specific libraries. Such RFLP markers will

contribute to increasing the resolution of the linkage map of the CF region, and ultimately to the identification of the CF gene itself.

We thank Marie-France de Tand, Chantal Foubert and Marie-Sylvie Gross for their technical assistance.

Note added in proof: Our recent linkage analysis shows that both CF and DOCRI-917 are closely linked to the pro α 2(1) collagen gene (7q21-q22) (ref. 22 N. Buchwald et al., in preparation).

A closely linked genetic marker for cystic fibrosis

Ray White*, Scott Woodward*, Mark Leppert*, Peter O'Connell*, Mark Hoff*, John Herbst†, Jean-Marc Lalouel*, Michael Dean‡ & George Vande Woude‡

Cystic fibrosis is a recessive genetic disorder, characterized clinically by chronic obstructive lung disease, pancreatic insufficiency and elevated sweat electrolytes; affected individuals rarely live past their early twenties. Cystic fibrosis is also one of the most common genetic diseases in the northern European population. The frequency of carriers of mutant alleles in some populations is estimated to be as high as 1 in 20, carrying a concomitant burden of about one affected child in 1,500 births. Because little is known of the essential biochemical defect caused by the mutant gene, a genetic linkage approach based on arbitrary genetic markers and family studies is indicated to determine the chromosomal location of the cystic fibrosis (CF) gene. We have now obtained evidence for tight linkage between the CF locus and a DNA sequence polymorphism at the *met* oncogene locus. This evidence, combined with the physical localization data for the *met* locus presented in the accompanying paper¹, places the CF locus in the middle third of the long arm of chromosome 7, probably between bands q21 and q31.

Appropriate families are required for genetic linkage analyses with recessive disease loci. For this study, we sampled and tested 13 families with multiple affected offspring. Siblings were characterized at cystic fibrosis clinical centres as affected or unaffected based on quantitative sweat chloride determination as well as other clinical features. Several of the families were from Utah, but most came from different regions in the United States.

We estimate that more than 100 loci have been tested for linkage in CF, including 21 probes from our own laboratory, with negative results. However, Eiberg et al. have reported evidence of linkage between the CF locus and the gene for the enzyme paroxonase², and recently Tsui and others have obtained evidence for genetic linkage with a DNA marker (L.-C. Tsui, personal communication). Both of these linkages are rather

Fig. 1 Segregation of the *TaqI* polymorphism in a complete three-generation family. DNAs from the indicated individuals were digested with the restriction enzyme *TaqI*, electrophoresed in agarose and transferred by the method of Southern to a nylon filter (Micon Separations, Inc.). The filters were hybridized⁹ with the clone *metH* (refs 1, 3). The polymorphisms were found by examination of a panel of DNAs from six unrelated individuals digested with the restriction enzymes *MspI*, *TaqI*, *EcoRI*, *HindIII*, *PstI* or *BclI*. Only *MspI* and *TaqI* revealed polymorphism. Individuals digested with *TaqI* yielded fragment lengths of either 7.5 kb (allele 1) alone or 4.0 kb (allele 2) alone, or both 7.5 and 4.0 kb. Digestion with *MspI* revealed individuals with fragment lengths of 2.3 and 1.8 kb, or only one of the two. In six informative families with large sibships, we found no exceptions to mendelian inheritance. A survey of 60 unrelated individuals gave a frequency of 0.56 for the 7.5-kb *TaqI* allele and the 2.3-kb *MspI* fragment, and 0.44 for each of the two smaller fragments. In all cases where phase could be distinguished, the large fragments were found together as a single haplotype, indicating a high degree of linkage disequilibrium in this marker system.

loose (10% and 15% recombination, respectively) but they do begin to pave the way for a more precise localization. Klinger has also reported suggestive, but not definitive, evidence for linkage of cystic fibrosis to a genetic marker located on the short arm of chromosome 21 in two large Amish pedigrees. However, the linkage was not evident when a collection of outbred nuclear families was examined (Klinger, personal communication). To develop a genetic marker at the *met* locus, we cloned fragment H (refs 1, 3), a 1.6-kilobase (kb) *SalI/EcoRI* fragment, into pBR322. Figure 1 shows the inheritance of a polymorphic *TaqI* restriction fragment revealed by this probe in a complete three-generation family. An *MspI* fragment also showed polymorphism with this probe. Of 60 unaffected unrelated individuals examined, 36 were heterozygous. However, we have seen only two haplotypes thus far.

At least one parent was heterozygous at the *met* locus in 12 of the 13 CF families investigated. Linkage tests between the CF locus and the *met* locus were performed with the computer program LINKAGE (ref. 4). Our results are reported in Fig. 2 and Table 1. As shown in Fig. 2, the LOD score reaches a maximum of 8.65 at a recombination value of 0, indicating no evidence for recombination. A LOD score of 8.65 corresponds to odds of $4 \times 10^8:1$, favouring the hypothesis of complete linkage over that of independent segregation. We also verified that in each family the LOD score is maximal under the hypothesis of complete linkage. As in all estimation situations, our sample estimate of the recombination rate between these two loci may depart from the true, unknown value because of sampling error. As indicated in Fig. 2, however, the true recombination frequency is unlikely to be $>5\%$. Our data therefore indicate tight linkage between cystic fibrosis and the *met* gene in these families.

Table 1 shows the composition, the genotypes at the *met* locus and the LOD score for each family. Under the hypothesis of

Table 1 Summary of family data

Family	Parents	Offspring	LOD score
1409	12×11	3A (11)	0.60
1414	12×22	3A (12)	0.60
1415	12×12	3A (11) 1N (12)	1.33
1422	12×11	3A (12)	0.60
1425	12×11	5A (12) 2N (12, 11)	1.15

1438	11×12	2A (11)	0.30
1442	12×11	3A (11)	0.60
1446	11×12	3A (11)	0.60
774	11×12	2A (11)	0.30
1378	22×12	3A (22) 2N (22)	0.25
1436	11×22	3A (12)	0.00

Genotypes at the marker locus reported for each family member. The LOD score for each informative family at a recombination value of 0 is also reported, allowing a closer inspection of the contribution of each family to the linkage evidence. Assuming that all parents are heterozygous at the CF locus, all but two (families 1415, 1427) are single backcrosses with respect to the test locus. In such families, each affected offspring contributes terms equal to θ and $1 - \theta$ under each parental phase respectively. Under complete linkage, phase information can be derived from a single affected individual. It follows that each additional individual will contribute 2 units to the odds ratio, or equivalently 0.301 to the LOD score, while the penalty of having to infer phase amounts to 0.301 LOD unit in each family. In two instances of such crosses, unaffected siblings were available for testing. In family 1425, five affected siblings have genotype 12, whereas two unaffected siblings have genotypes 12 and 11, respectively. Without the unaffected siblings, the LOD score would have been 1.20 instead of 1.15. The two unaffected siblings, while compatible with the hypothesis of no recombination, have discordant genotypes at the test locus and contribute terms $(2 - \theta)(1 + \theta)$ under each parental phase, accounting for -0.05 in LOD units. In family 1378, the contribution of three affected offspring is offset by two unaffected siblings with the same genotype at the *met* locus, each unaffected sibling accounting for terms $(2 - \theta)$ and $(1 + \theta)$ under each phase. Family 1427 is a double intercross and contributes more support to the hypothesis of complete linkage than any other family. This results from the increased contribution of affected individuals of genotype 11 in this intercross as opposed to the backcrosses, as well as from the information provided by the four unaffected siblings of genotype 12. Once an affected individual has yielded phase, each additional affected sibling of genotype 11 contributes $(1 - \theta)^2$, or 0.602 LOD units, while each unaffected sibling of genotype 12 contributes $2(1 - \theta + \theta^2)$, or 0.125, to the overall LOD score. Family 1415 is similar, but includes only one unaffected sibling of genotype 12.

complete linkage, we can derive the parental phases from the genotypes of the affected offspring. This reveals that 19 of the 26 parental chromosomes carrying the CF allele also carry allele 1 at the *met* locus, while only 11 of 26 parental chromosomes carrying the normal allele at the CF locus carry allele 1 at the *met* locus, which is marginally significant ($\chi^2_1 = 3.86$, $p = 0.05$). The allelic distribution at the *met* locus among the latter chromosomes does not differ significantly from that observed among 60 chromosomes tested in a random Utah control panel ($\chi^2_1 = 0.98$). When these chromosomes carrying a normal allele at the CF locus are pooled and contrasted to the chromosomes carrying the CF deleterious allele, heterogeneity with respect to the *met* alleles 1 and 2 is no longer significant ($\chi^2_1 = 2.71$). Judgment regarding possible allelic association must await the characterization of additional CF families.

The apparent close genetic linkage found in family studies suggests an upper limit of 5% on the genetic distance between the CF locus and the *met* locus. The absence of recombinants between the CF locus and the *met* locus in our study does not support the hypothesis that cystic fibrosis can be caused by mutations at more than one locus. However, ours is still a limited sample and it is important to test many more families to place a more restrictive upper limit on the possible frequency of cystic fibrosis caused by mutations at other loci.

Although the *met* locus is potentially useful as a prenatal diagnostic marker for cystic fibrosis in families known to be at risk, several additional data must be developed before such application. First, more CF families with large sibships must be tested, to refine the genetic distance as well as to detect locus heterogeneity. Observation of a subset of families showing no linkage to the *met* locus could reveal locus heterogeneity. These data will be essential for providing quantitative estimates of

Fig. 2 LOD score for linkage between cystic fibrosis and the *met* locus as a function of recombination fraction. A recessive model with complete penetrance was assumed for cystic fibrosis, with a frequency of 0.025 for the deleterious allele. The results were unaltered over a wide range of allelic frequencies. The test marker was treated as a co-dominant, two-allele system, with gene frequencies of 0.56 and 0.44 for alleles 1 and 2, respectively. The *TaqI* polymorphism was scored as the primary genetic marker and was corroborated by the *MspI* polymorphism. The LOD score is computed as the decimal logarithm of the probability of the observations for a given value of the recombination fraction divided by the corresponding probability under the assumption of no linkage. This probability ratio measures our degree of belief in the hypothesis of linkage at the assumed value relative to the hypothesis of independent segregation. Rather than a standard error based on large sample theory, the use of an empirical confidence region based on the observed LOD score distribution has been recommended¹⁰. A one-unit support limit is obtained by finding that value of the recombination fraction for which the LOD score is decreased by one unit, defining a range of the recombination value for which the odds remain within 10 to 1 of the maximum. This yields an empirical bound for the recombination fraction of 0.051 in our sample. Values for recombinant fraction θ of 0, 0.01, 0.05, 0.10, 0.20, 0.30 and 0.40 produced respectively values for $z(\theta)$ of 8.65, 8.46, 7.66, 6.64, 4.52, 2.41 and 0.70.

individual risk. Second, the extent of polymorphism must be improved so that the marker locus has more than two alleles. At present, many individuals at risk would be unable to obtain useful information. Third, if, as we expect, some recombinants between the *met* and CF loci are found, it will be important to develop a genetic marker locus on the other side of the CF locus to detect recombination events in the region. Until these conditions are met, diagnostic applications are premature.

The fact that no recombinants between the *met* gene locus and the CF locus have yet been identified suggests that the two are indeed very close and even raises speculation that the *met* gene might actually be the cystic fibrosis gene. Furthermore, because the product of the *met* gene is a membrane-spanning receptor protein showing tyrosine kinase homology¹, characteristics which might also be expected of a gene causing a chloride ion-exchange defect, in retrospect *met* might have been considered a candidate gene for the disease. However, although we cannot exclude the *met* gene as a candidate for the CF gene, aetiological involvement of the *met* gene in cystic fibrosis is unlikely: the close linkage still permits a span of more than 1,000 kb within which to place the CF gene and as many as a hundred genes may be located within so wide a region. It is nonetheless interesting that the *met* gene bears homology with the insulin receptor¹, located on chromosome 19 very near the low-density lipoprotein (LDL) receptor⁵; this homology may suggest that these are members of a clustered family of genes. By this reasoning, although not itself the CF gene, *met* could

open the way to identifying a family of closely linked genes of which one may be the gene for cystic fibrosis.

The most significant aspect of the localization of the CF gene is the impetus it provides to efforts to identify and clone the gene. New techniques make it feasible to cover the large distances that are likely to be involved. Pulse-field gel electrophoresis⁶ and new, rapid 'walking' techniques⁷ suggest approaches to moving closer to the gene. Recent advances in cell culture technology that permit *in vitro* growth of cells which maintain the CF phenotype⁸ suggest the possible invention of protocols that could provide functional assays for regions that might encompass the gene. We hope that identification of the CF gene will permit identification and analysis of the biochemical pathway which is perturbed by mutations in the gene, and will suggest rational means of intervention and management of this disease.

We thank Barbara Ogden for assistance in family collection, Tara Bragg, John Cowan, Russell Eldridge, Mary Hadley, Leslie

Jerominski, Lesa Nelson and Leslie Sargent for technical assistance, Carol Wood of the Intermountain Cystic Fibrosis Center for assistance in family collection, the NIGMS Human Genetic Mutant Cell Repository for lymphoblastoid cell lines of family 774, and Ruth Foltz for editorial assistance in preparing this manuscript. M.D. is an American Cancer Society postdoctoral fellow.

Cystic fibrosis (CF) is the most common genetic disease in Caucasian populations, with an incidence of 1 in 2,000 live births in the United Kingdom, and a carrier frequency of approximately 1 in 20. The biochemical basis of the disease is not known¹, although membrane transport phenomena associated with CF have been described recently². Consanguinity studies have shown that the inheritance of CF is consistent with it being a recessive defect caused by a mutation at a single autosomal locus³. Eiberg *et al.*⁴ have reported a genetic linkage between the CF locus and a polymorphic locus controlling activity of the serum aryl esterase paraoxonase (PON). The chromosomal location of PON, however, is not known⁴. Linkage to a DNA probe, DOCR1-917, was also recently found at a genetic distance of ~15 centimorgans (L.-C. Tsui and H. Donniss-Keller, personal communication), but no chromosomal localization was given. Here we report tight linkage between the CF locus and an anonymous DNA probe, pJ3.11, which has been assigned to chromosome 7cen-q22.

The use of DNA probes allows the determination of linkage between a restriction fragment length polymorphism (RFLP) and a mutated locus causing pathology, even when the biochemical defect is unknown. We have used this approach successfully to analyse sex-linked diseases such as Duchenne mus-

Fig. 1 Map of human chromosome 7, showing the chromosomal locations of probes *TCRβ* (ref. 9), *COL1A2* (ref. 25) and pJ3.11 (ref. 18).

cular dystrophy⁵; it has also been used to study previously unassigned autosomal dominant diseases such as Huntington's chorea⁶ and adult onset polycystic kidney disease⁷. However, although linkage has been attempted with DNA markers to autosomal recessive diseases of unknown biochemical aetiology, only exclusions have been achieved to date.

There have been few clues to the chromosomal localization of the CF locus. Mayo *et al.*⁸ suggested that the CF locus might be localized on chromosome 4, based on data from cell hybrids expressing a ciliary dyskinesia factor, but this was subsequently shown to be unlikely by exclusion mapping with several DNA and protein markers⁹. Two different families have been reported to show both chromosomal anomalies and CF; the study of one of these families suggested that the CF locus mapped to 5p, whereas in the other family it was mapped to 13q34 (ref. 10). We investigated the latter family by mapping the gene for clotting factor X to 13q34 (ref. 11) and then excluded CF from linkage to factor X¹². We have also excluded the candidate gene coding for complement component 3 by showing that alleles for an

Table 1 LOD scores at various recombination fractions (θ) for the relationships between the CF locus (CF) and the locus defined by pJ3.11 and between CF and *TCRβ*

Marker	No. of meioses	$\theta = 0$	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45
CF versus J3.11	27	5.24	4.52	3.80	3.09	2.41	1.77	1.20	0.77	0.33	0.11

Combined LOD scores were calculated using the computer program package LINKAGE as described by Lathrop²⁴.

Fig. 2 Segregation of the *Msp*I polymorphism defined by pJ3.11 with the CF locus in a family with three affected (solid symbols) and three unaffected (open symbols) children. The RFLP alleles are 4.2 kilobases (kb) (A1) and 1.8 kb (A2) long; the frequency of the rare allele A1 is 0.2 (ref. 26).

Methods. DNA (5 µg) from 10 informative families with two or three affected children was digested with *Msp*I and fractionated by electrophoresis on 0.8% agarose gels by standard methods⁹. Fractionated DNA was transferred to Hybond membranes (Amersham International) and hybridized⁹. The probe used was the 500-bp *Hind*III-*Eco*RI fragment from the insert of pJ3.11, labelled to a specific activity of 1×10^9 d.p.m. µg⁻¹ by synthesis using random oligonucleotide primers. Blots were washed to a final salt concentration of 0.15 M NaCl in the presence of 0.2% SDS. Autoradiography was for 16 h at -70° using double-intensification screens.

RFLP detected by this sequence do not co-segregate with cystic fibrosis in families with multiple affected sibs¹³. Several groups have reported extensive linkage exclusions between the CF locus and protein and DNA markers¹⁴⁻¹⁶, which in total exclude ~40% of the human genome.

We have tested for linkage between the CF locus and multiple markers on a single human chromosome by multipoint linkage analysis¹⁷. As part of our attempt to study human chromosomes for which few exclusions had been obtained for cystic fibrosis, we have examined the linkage relationships of the two DNA markers located on chromosome 7 to the CF locus. These are the anonymous DNA segment pJ3.11, which defines an *Msp*I polymorphism and has been mapped to 7cen-q22 by somatic cell hybrid panels¹⁸, and the T-cell receptor β -chain (*TCR* β) gene which defines *Bgl*II polymorphism and maps to 7q3 (ref. 19). These localizations are summarized in Fig. 1.

The linkage relationships between the two markers and the CF locus are shown in Table 1. The maximal LOD score between the locus defined by pJ3.11 and the CF locus calculated for combined sexes is 5.24 at a recombination fraction (θ) = 0 (99% confidence interval 0-13 centimorgans). A LOD score of 3.0 is accepted as a sufficient statistic to prove synteny between two loci²⁰. No recombinants between the probe and the CF locus have been observed in 27 meioses. A typical pedigree is shown in Fig. 2. All informative pedigrees and typings are available from the authors.

TCR β (7q3) shows significant linkage (for two syntenic loci²¹) to the CF locus at a genetic distance of 10 centimorgans. We have also demonstrated that the collagen locus *COL1A2* is linked to the CF locus at a genetic distance of ~10 centimorgans²², suggesting that *COL1A2* (7q22) and *TCR* β (7q3) may flank the CF locus, as they are not themselves closely linked. We are presently analysing the linkage between pJ3.11, *TCR* β and *COL1A2* in large reference pedigrees (Centre d'Etude Polymorphisme Humain), as well as in cystic fibrosis families which have been typed for *PON*.

Genetic heterogeneity of the locus mutated in cystic fibrosis (as opposed to multiple mutations causing a defect at a single locus) would be demonstrated by the observation of heterogeneity in the linkage relationship in different families between a given close marker and the CF locus. The informative families in this study originated from Australia, Eire, France,

West Germany, United Kingdom and Pakistan. All the families show tight linkage between the pJ3.11 probe and the CF locus. It would be of interest to study these probes in the Amish kindred reported by Klinger²³, as there are data indicating differences in linkage for that family compared with those studied here (K. Klinger, personal communication). A more extensive analysis covering different populations is in progress.

The pJ3.11 probe is presently informative in approximately 40% of matings and, given the tight linkage demonstrated here, would provide accurate heterozygote detection and antenatal diagnosis of cystic fibrosis in some cases. However, such diagnoses will be facilitated markedly when the availability of a set of informative and ordered flanking markers (*PON*, pJ3.11, *COL1A2*, and *TCR* β) has been confirmed.

We thank the Cystic Fibrosis Research Trust, and especially Ron Tucker, the MRC and the Foulkes Foundation for consistent and generous financial support, and our many clinical colleagues and the CF families for their help in obtaining and giving samples. We particularly thank Kay Davies, Lap-Chee Tsui, Kathy Klinger, Veronica van Heyningen and Nigel Spurr for helpful discussions, and for providing data in advance of publication.

The *met* oncogene was previously isolated from a chemically transformed human cell line, MNNG-HOS (refs 1, 2). Recent evidence has demonstrated that two classes of transcripts are expressed from the *met* proto-oncogene locus. The *met* oncogene, however, expresses an aberrant RNA which has sequences in common with both transcripts. We now report partial nucleotide sequencing of the human *met* oncogene and show that *met* is

related to the protein kinase oncogenes and growth factor receptors. The *met* nucleotide sequence is not identical to that of any published gene, and it is more closely homologous to the tyrosine kinases than to the serine/threonine kinases. Within the tyrosine kinase family, the sequenced *met* domains are most closely related to the human insulin receptor and the viral *abl* gene. *In situ* chromosome hybridization has mapped *met* to human chromosome 7 band 7q21-q31, a location distinct from that of other kinases. This is also a region associated with nonrandom chromosomal deletions observed in a portion of patients with acute non-lymphocytic leukaemia. The accompanying paper³ shows that this chromosomal locus is also tightly linked with the human hereditary disease cystic fibrosis.

To characterize the *met* oncogene and its protein product(s), we have sought to determine the nucleotide sequence of coding portions of the locus. The sequences required for transformation by *met* are contained within 35 kilobases (kb) of human genomic DNA and NIH 3T3 cells transformed with *met* express a 6.5-kb messenger RNA^{1,4}. Initial attempts to isolate a complementary DNA copy of this RNA generated a 2.0-kb clone. However, the partial nucleotide sequence indicated that this clone contains only untranslated sequences (M.P., data not shown). As an alternative approach, a 9-kb fragment was cloned into a retrovirus vector derived from Moloney sarcoma virus (Fig. 1).

Retroviral vectors have been shown to process segments of genomic DNA, generating cDNA-like copies⁵. We hoped that by cloning a segment of *met* genomic DNA into such a vector we could recover a clone devoid of intervening sequences. An *S*₁ nuclease experiment revealed that passage of this segment of *met* genomic DNA through a retroviral intermediate resulted in the excision of at least one intervening sequence; the recovered clone protected a fragment 1–200 bases longer than the corresponding segment of genomic DNA (data not shown). Nucleotide sequencing of the recovered clone and the corresponding portions of genomic DNA revealed an open reading frame 126 amino acids long (Fig. 2A). When this putative *met* amino-acid sequence was used to search an amino-acid sequence database, homology with several tyrosine kinase oncogenes and growth factor receptors was revealed (Fig. 2B).

In addition, we have also determined the nucleotide sequence of a 1.1-kb fragment of genomic DNA from the middle of the *met* oncogene (fragment D) which is known to hybridize with *met* mRNA transcripts². This sequence contained an open reading frame bounded by splice acceptor and donor signals which shows dramatic homology to the tyrosine kinases (Fig. 2). Figure 2B compares the amino-acid sequence of the two open reading frames with several members of the tyrosine kinase family. The putative exon is identical in 18/23 residues with the human insulin receptor^{6,7} and in 15/23 amino acids with the virus *abl*

Fig. 1 Sequencing strategy of the *met* oncogene. **A**, Genomic DNA located at the 3' end. Filled areas depict coding regions or putative exons. **D** and **G** refer to fragments described previously^{1,2}. Both strands of the expanded regions were sequenced by the chain-termination method²⁶. The 9-kb *SalI* fragment inserted into the retrovirus vector is depicted by the arrows. **B**, *met* sequences contained within the spliced clone recovered. **R**, *EcoRI*; **P**, *PstI*; **S**, *SalI*.

Methods. The 9-kb *SalI* fragment was cloned into pGV16 (ref. 27), which was modified to accept *SalI* fragments by inserting a *SalI* linker. Virus was rescued from this plasmid by co-transfection with an equal amount of pMOV-3 plasmid²⁸ into NIH 3T3 cells. Infected NIH 3T3 cells were subsequently selected for resistance to G418 using 500 $\mu\text{g ml}^{-1}$ Geneticin (Gibco). The viral DNA from the transfected cells was recombined by fusing G418-resistant NIH 3T3 cells with COS cells using polyethylene glycol as described previously²⁹. Hirt supernatants³⁰ were prepared after 72 h and used to transform *Escherichia coli* strain HB101 (BRL) using the procedure described by Hanahan³¹ and selected on kanamycin (35 $\mu\text{g ml}^{-1}$). Only colonies which hybridized to the *G* fragment probe (see text) were analysed.

gene⁸. This region is highly conserved among all members of the tyrosine kinase family⁹, and moderately conserved between other kinases such as *mos* (ref. 10) (Fig. 2B), *raf* (ref. 11), the yeast CDC28 protein¹² and cyclic AMP-dependent kinase¹³. Although the two exons at the C-terminus of *met* contain a region which is less well conserved among kinases⁹, certain portions of this domain are conserved among all members of the family, including *met* (Fig. 2B).

We have previously demonstrated that although *met* maps to chromosome 7, it is not the *erbB*/epidermal growth factor (EGF) receptor gene, which is located at chromosome 7 p12-p14 (refs 1, 14). To map the location of *met* on chromosome 7 more precisely, we performed *in situ* chromosomal hybridization. A ³H-radiolabelled *met* probe was hybridized to metaphase cells

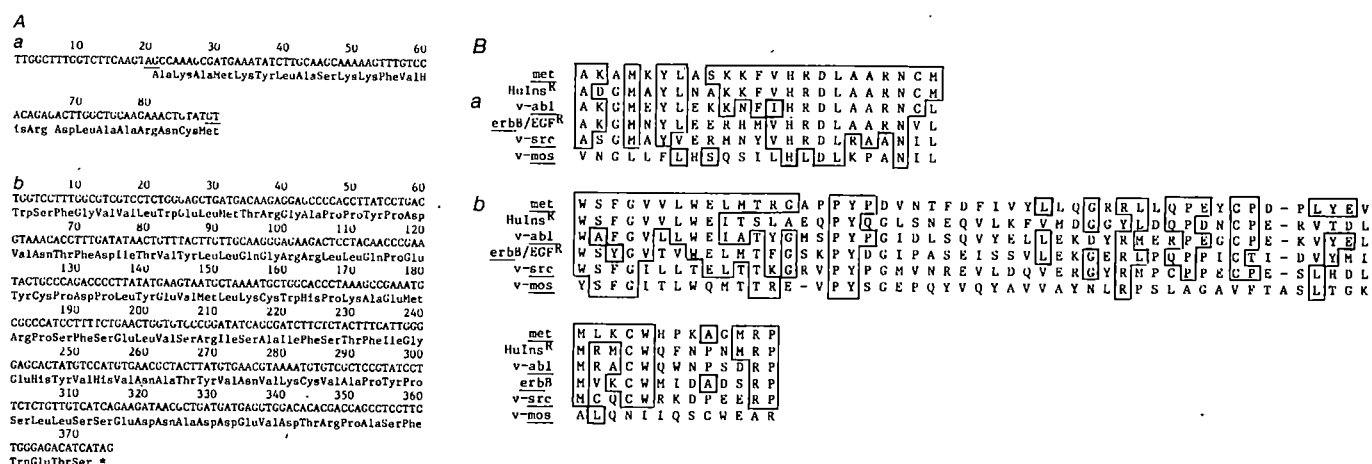

Fig. 2 Partial nucleotide sequence of the *met* oncogene. **A**, The nucleotide sequence and inferred amino-acid sequence of portions of *met* are shown: **a**, putative exon from **D** fragment; **b**, open reading frame of the last two exons. Putative splice signals are underlined. **B**, Comparison of the *met* amino-acid sequence with corresponding regions of the human insulin receptor (Hu InsR)^{6,7}, viral *abl* oncogene⁸, human EGF receptor³², and viral *src* and human *mos* proto-oncogenes^{10,33}.

Fig. 3 *In situ* chromosomal hybridization of the *met* oncogene. **A**, Distribution of labelled sites in 100 normal metaphase cells. Human metaphase cells prepared from phytohaemagglutinin-stimulated peripheral blood lymphocytes were hybridized with the ^3H -labelled E probe¹. Specific labelling was observed on chromosome 7 at bands q21–q31. **B**, Distribution of labelled sites on chromosome 7. Of 100 metaphase cells examined, 19 (19%) were labelled on bands q21–q31 of chromosome 7. Of a total of 36 grains on chromosome 7, 21 or 58% were located on q21–q31; these sites represented 8.2% (21/256) of all labelled sites ($P > 0.005$). A modification of the method of Harper and Saunders was used^{34,35}.

from phytohaemagglutinin-stimulated peripheral blood lymphocytes. Figure 3A shows the distribution of grains observed in 100 metaphase cells. A significant clustering of grains was observed on the long arm of chromosome 7 at bands q21–q31 ($P < 0.005$); no other chromosome showed specific labelling. Of the 100 metaphase cells examined, 19 were labelled on bands q21–q31 of one or both of the chromosome 7 homologues (Fig. 3B); these sites represented 8.2% (21/256) of all labelled sites. The largest cluster of grains was observed at band 7q22. Specific labelling was also observed at this chromosomal region when *met* was hybridized to metaphase cells from peripheral blood lymphocytes obtained from a second individual. Of 50 metaphase cells examined, 10 showed label on one or both chromosome 7 homologues, representing 7.1% (12/169) of all labelled sites. These results confirm the location of this gene on the long arm of human chromosome 7 and refine the location to band q21–q31.

We conclude that the *met* oncogene is a member of the tyrosine kinase family, although analysis of the *met* protein product will be required to establish whether it possesses this activity. Analysis of *met*-related mRNAs has revealed that the transforming gene expresses a hybrid truncated mRNA⁴. Thus, we speculate that the *met* oncogene transforms cells by expressing a truncated form of the kinase encoded by the proto-oncogene. A similar mechanism appears to be responsible for the activation of both the *v-erb-B* and *c-erb-B*/EGF receptor genes^{15,16}, and the *bcr/abl* gene in chronic myelogenous leukaemia¹⁷.

The homology between *met* and the kinase domain of the insulin receptor is intriguing. Insulin is a member of a gene family which includes insulin-like growth factors I and II and nerve growth factor¹⁸. Similarly, there are several distinct receptors for insulin-related mitogens¹⁹. It has not escaped our attention that the *met* class I gene product may encode a receptor for an insulin-like peptide. However, *met* is also closely related to *abl*. Identification and characterization of the *met* protein(s) should help address these interesting questions.

Nonrandom deletions of the long arm of chromosome 7 are frequently observed in the leukaemic cells of patients with acute non-lymphocytic leukaemia (ANLL). Interestingly, *met* was isolated from a human cell line (HOS) transformed with the chemical carcinogen *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, and increasing evidence now relates the development of ANLL

to mutagen exposure both in patients subjected to cytotoxic therapy for a primary malignancy and in patients exposed to environmental carcinogens^{20,21}.

It is notable that recurring abnormalities involving chromosome 7 are common in such patients. These abnormalities include loss of a whole chromosome 7 or of part of the long arm of this chromosome, del(7q) (refs 20, 22). It may be significant that *met* is located in the region of the proximal breakpoint of the interstitial deletions of 7q observed in patients with ANLL²³.

In the accompanying paper, White *et al.*³ describe restriction fragment length polymorphisms (RFLPs) from the *met* locus which were developed for examining ANLL patients. They find that these RFLPs are tightly linked to the hereditary disease cystic fibrosis (CF). The *in situ* chromosomal mapping of *met* thus localizes the CF locus in man. At the very least then, *met* is a marker for CF, a disorder that is speculated to involve an ion-channel imbalance²⁴. However, we show here by sequence homology that *met* is a member of the tyrosine kinase family and we note that tyrosine kinase receptor activation has been linked to the regulation of the sodium ion–proton antiporter²⁵. We also note that the *met* proto-oncogene locus expresses two transcripts which appear to be noncoordinately expressed overlapping transcripts³. The genomic sequences encoding these two transcripts could cover greater than several hundred kilobases. Present genetic data³ suggest that the distance between *met* and the CF locus is less than 5,000 kb.

We thank Doug Ludtke and Martin Schmidt for assistance with DNA sequencing, Chris Westphal and Linda Miller for technical assistance, and Friedrich Propst for help with the computer analysis. Immunoglobulin-binding factors are known to regulate the synthesis of B-cell-derived immunoglobulin heavy-chain isotypes¹. Cloning and nucleotide sequence determination of complementary DNA encoding rodent IgE-binding factors (IgE-BF) revealed that messenger RNA encodes a glycoprotein of 557 amino acids which is expressed as a precursor of relative molecular mass (M_r) 60,000 (60K) in COS7 monkey cells². We report here that the 3' two-thirds of the IgE-BF coding sequence shows a surprising homology (72%) at the DNA level with coding sequences of the *gag* and *pol* (DNA endonuclease) genes of the Syrian hamster intracisternal A particle (IAP H18)³, an endogenous retrovirus. This marked homology demonstrates that the rodent gene encoding IgE-BF is a hybrid gene which evolved very recently by integrating genes of viral origin, and that the encoded polypeptide comprises three separate domains: an IgE-BF domain and retrovirus-derived *gag* and DNA endonuclease-like domains. This may represent the first report of a cellular gene containing a virus-derived coding sequence.

Figure 1 shows a homology matrix comparison between the nucleotide sequence coding for the rodent IgE-BF and that of

the Syrian hamster IAP genome³. A striking homology with IAP is found for the 3' two-thirds (nucleotides 700-1,770) of the IgE-BF coding sequence, whereas the remaining region (1-699) shares no obvious homology with IAP. In IAP, the homology extends over two regions (nucleotides 1,483-2,140 and 5,364-5,772) which are interrupted by a non-homologous sequence of ~3,200 nucleotides bounded by direct repeats of non-identical but homologous sequences (2,142-2,185 and 5,364-5,406). This non-homologous sequence is completely absent in the IgE-BF coding sequence (Fig. 1b). The direct repeats may result in the deletion of a large region of DNA in the IgE-BF coding sequence. The 5' homologous region of IAP exists within the *gag* coding region, while the 3' block contains part of the DNA endonuclease coding sequence^{3,4}. Alignment (Fig. 2) of the nucleotide sequences reveals 72% homology at the DNA level. Martens *et al.*² noted that the deduced amino-acid sequence of the IgE-BF precursor polypeptide shows local homology with retroviral *pol* gene products in the C-terminal region of 50 amino acids. This high degree of sequence homology indicates unequivocally that the two sequences are evolutionarily related.

These results strongly suggest that the rodent IgE-BF precursor comprises two components of distinct origin: the N-terminal one-third (amino-acid positions 1-202) carries a function unique to IgE-BF while the remaining C-terminal portion consisting of *gag* (203-422) and DNA endonuclease (423-557) related domains was derived from a retrovirus or endogenous retrovirus very recently during evolution. That the IgE-BF coding sequence shows a high degree of nucleotide sequence homology with the rodent IAP, together with the existence of *pol*-related sequences in various retroviruses and transposons across a wide taxonomic distance⁴⁻⁹, strongly suggests that a certain type of retrovirus or endogenous retrovirus was inserted into a cellular DNA region proximal to the primordial IgE-BF gene, and these were later

Fig. 1 Nucleotide sequence homology between the rodent IgE-BF coding sequence and the Syrian hamster IAP (H18). a, Homology matrix comparison. Each diagonal line indicates a segment 30 nucleotides long that shows homology >60%. b, Diagram showing the location of the homologous regions connected by slanted lines. The open reading frames (ORFs) corresponding to the retroviral *gag* and *pol* genes are also shown.

A major retroviral core protein related to EPA and TIMP

WE add another curious note to the sequence similarities shared by the proteins identified by biological properties as either the erythroid-potentiating activity (EPA) factor associated with stimulation of erythroid precursors¹ or the tissue inhibitor of metalloproteinases (TIMP). A recent report by Docherty *et al.*² demonstrates that these two proteins have identical sequences.

Using the Intelligenetics PEP program, we have detected regions of similarity between the EPA-TIMP protein and the gag core proteins encoded by retroviruses including human T-cell lymphotropic virus types I, II and III (HTLV-I, -II and -III), bovine leukaemia virus (BLV), Rous sarcoma virus (RSV) and Moloney murine leukaemia virus (Mo-MuLV). These regions are congruent with those conserved among the major retroviral capsid proteins.

These gag proteins are highly divergent among themselves at both the primary and secondary structure levels as predicted by hydrophilicity profiles (Hopps and Woods algorithm)³. Table 1 shows the alignment of the amino-acid sequences, while Fig. 1 shows that the relative position of the regions of similar sequence in the respective proteins is the same. The similarities in sequence and sequence organization may reflect either a common evolutionary origin or common function. It is noteworthy that the only region of sequence similarity between EPA and the human granulocyte-macrophage colony-stimulating factor⁴, besides a short hydrophobic stretch close to the amino terminus, is region III, which is also the most highly conserved region among the retroviral core proteins.

The similarities reported here open the possibility that the major gag core protein may be important not only in viral assembly but also in affecting the cellular physiology so as to favour viral replication

Fig. 1 Regions of similarity between EPA-TIMP and the major retroviral gag core proteins. aa, Amino acids.

acting as a growth factor or a protease inhibitor. In the latter case it could prevent the breakdown of proteins essential for viral replication such as reverse transcriptase or the endonuclease-integrase. These proteins are exposed to the cytoplasmic and nuclear environments during the early stages of the infection process. The major retroviral core protein may also regulate changes in the cytoskeleton during the process of budding. In this regard we note that certain pathogenic determinants of some avian and murine retroviruses have been mapped to the gag-pol region^{5,6}. Using an analogy with the gag core protein function, EPA-TIMP may interact with RNA and with membrane proteins in its regulatory activity.

Many of the transforming oncogenes transduced by retroviruses are synthesized as fusion proteins that contain a substantial portion of the major capsid protein. The deletion of the gag determinants in some cases results in loss of transforming activity¹³ which could be due to loss of growth-promoting or protease inhibitory activities associated with the gag portion of the fusion product.

Body size and biomass

A RECENT article¹ described several examples of the double logarithmic relationship between the number of individuals and their body length for mixed arthropod populations resident on vegetation of various surface fractal dimensions. Eight examples were given graphically spread over five diagrams. The mean of the slopes of the regression lines through the diagrams can be derived, from the individual slopes given¹, as -3.028 ; that is within 1% of -3 . A slope of -3 indicates a relation of the form: $\log N = \log K - 3 \log L$, where N is the number of individuals, K is constant and L is a body length; that is, $N = KL^{-3}$.

However, if we assume a constant body shape and that all arthropods enjoy a uniform density for a first approximation, we have: $m = k_0 L^3$, where m is body weight and k_0 is a constant. This converts to $L = k_1 m^{1/3}$, where k_1 is a constant. Therefore, $N = K(k_1 m^{1/3})^{-3} = k_2 m^{-1}$ where k_2 is a constant. But $m = M/N$, where M is the total biomass of all N individuals of a given size. Therefore, $N = k_2(M/N)^{-1} = k_2(N/M)$; that is, $M = k_2$. In other words, the biomass of individuals of one size, summed over all species within a community of mixed arthropods, is constant.

I thank Professor J. H. Lawton for helpful discussions on this matter.

Polarity reversal in the Solomon Islands arc

IN a recent letter, Cooper and Taylor¹ present evidence for two juxtaposed Wadati-Benioff zones in the Solomon Islands, and state that the seismic data provide the first direct evidence of a reversal of subduction polarity at an island arc.

The concept of arc polarity has received considerable attention in the literature²⁻⁴, particularly as such studies suggest how the tectonic settings of former volcanic belts might be interpreted. Cooper and Taylor, following the observations of other researchers on the two seismic zones in the Solomons⁵⁻⁸ raise one of the fundamental tectonic problems for this region, but in doing so fail to give perspective to their proposal by highly selective referencing—ignoring many contributions which might negate or modify their conclusions—and by greatly simplifying the dating of Tertiary volcanism in the region.

Central to the thesis of Cooper and Taylor is the concept that the Ontong Java Plateau collided with the North Solomon Trench sometime during the Miocene. A number of researchers who have been actively working in the Solomons have, over the last decade or so, questioned to varying degrees the concept of collision⁹⁻¹³ and there are strong geological grounds for suggesting that the Solomon Islands may represent the leading edge of the Ontong Java Plateau¹³⁻¹⁵. If two initially quite separate crustal blocks collided, the question rises as to where this collision zone is to be located so that it is in accordance with the known geology.

Arc polarity reversal in the Solomons is often associated with the collision model, following a widely quoted paper by Halunen and Von Herzen¹⁶. Yet what has received far less attention is that one of the major pieces of evidence cited by Halunen and Von Herzen in support of arc polarity reversal (high heat flow on the south-west flank of the Solomons) is more likely associated with the Woodlark Spreading Zone^{17,18}. The presence of an incipient seismic zone dipping south-west below Santa Isabel is interesting, yet its absence to the north along Bougainville requires special pleading by Cooper and Taylor. That this incipient seismic zone is a remnant subduction zone is one of a number of possibilities and until new geological evidence is forthcoming, I agree with Coleman¹⁹ that the concept of north-east-facing arc polarity in the Solomons during the Palaeogene is not proven.

Cooper and Taylor state, as support for their model of collision and polarity reversal, that there was a hiatus in arc volcanism lasting from late-early to early-late Miocene. However, on many of the islands, evidence for the age of volcanism is very poor and no clear age groupings may be given. On Bougainville the Kieta volcanics are dated as Oligocene? to lower Miocene?²⁰, though it is noted that unconsolidated equivalents at Kanga Hill range through to possible Pliocene age. Unnamed volcanics are equated in age with either the older Kieta volcanics or the younger Emperor Range volcanic beds merely on their location and erosional state, while the Buka Formation is dated on geomorphic evidence alone.

In the Shortland Group, volcanism is considered to be pre-Pliocene²¹; Turner and Ridgeway emphasize the lack of fossil and radiometric age control on the various volcanic episodes. It has been suggested that in the New Georgia Group volcanism commenced during the Pliocene¹⁸, though there is evidence for volcanism extending well back into the Miocene^{21,22}. On Choiseul²³ the oldest preserved post-basement sediments were deposited in the late Oligocene to early Miocene and, during early and middle Miocene, these contained increasing amounts of andesitic volcanic material. Possibly the best

evidence for a hiatus in arc volcanism comes from Guadalcanal²⁴ where the top of the Suta volcanics is placed on the Aquitanian-Burdigalian boundary. However, the age of the base of the Gold Ridge volcanics is uncertain and Hackman²⁴ notes that Suta-type volcanism continued intermittently in north-central Guadalcanal into the Pliocene. For San Cristobal, any deduction regarding the tectonic position of the island from Oligocene time onward that is based solely on the absence of arc volcanism in its stratigraphical record, is likely to be incorrect. In complex island arc settings, such as the Solomons, with rapid facies variation, localized unconformities, spasmodic volcanic episodes, and the paucity of age controls on volcanism, it is premature to make emphatic statements about breaks in volcanism and then to use the assertions to lend support to the notion of collision and arc polarity reversal.

The suggestion by Cooper and Taylor that volcanism on Savo may be the product of reactivated magmatism associated with a relic slab is not supported by petrological data¹³. The broad similarities in petrography, mineralogy and geochemistry between lavas from Savo, north Guadalcanal and Vella Lavella suggest, as a working hypothesis, that the same tectonic and magmatic phenomena have been responsible for the style of volcanism in these three localities.

Finally, I draw attention to the warnings of Arculus and Johnson²⁵ and make a plea that tectonic models proposed for island arcs such as the Solomons should balance generalized arc models carefully with the unique features as displayed in the field evidence and field relations of this enigmatic fractured island chain.

TAYLOR AND COOPER REPLY—Ramsay rightfully asserts that we did not cite many conflicting articles on the geology of the Solomon Islands in the short introduction to our paper¹.

There are two completely opposite interpretations of Solomon Islands geology. Ramsay² and Turner³ champion the interpretation that the Cretaceous oceanic basement on Malaita, Santa Isabel, Choiseul and Guadalcanal is similar, that the post-Eocene sediments on Malaita and Santa Isabel include fine-grained products of volcanism on Choiseul and Guadalcanal, and that an Oligocene arc was built on the leading edge of the Ontong Java Plateau above a north-east-dipping subduction zone. In contrast, Kroenke^{4,5} and Coleman^{6,7} champion the interpretation that whereas the unmetamorphosed basement and pelagic sediments of Malaita and Santa Isabel are similar to those of the Ontong Java Plateau, they are quite different from the metamorphosed basement and volcanoclastic sediments of Choiseul and Guadalcanal, requiring a Miocene collision between the two provinces, involving obduction of the former above a south-west-dipping subduction zone. The first group interpret the *en echelon* fault-bounded, peridotite-gabbro Korighole trend as a structural high forming a sediment barrier between the two provinces, whereas the second group interpret the same feature as the suture between the two provinces. The geology is sufficiently complicated that some authors including Coleman⁶⁻⁸ and Hughes and Turner^{3,9} have published self-contradictory interpretations. Thus, the evidence from Solomon Islands geology alone for a north-east-facing middle Tertiary arc which collided with the Ontong Java Plateau in the Miocene is ambiguous⁸ and open to conflicting interpretations^{2,3,5,7}.

Other evidence presented by Halunen and Von Herzen¹⁰ in support of arc polarity reversal includes the high heat flow and high shear-wave attenuation on the Solomon Sea side of the arc, the location of active volcanoes on the south-west side of the islands very close to the New Britain-San Cristobal trench, and the presence of deep (>400 km) earthquakes beneath the islands. Taylor and others^{8,11,12} have already noted that most of these phenomena are the result of active seafloor spreading in the Woodlark Basin and subduction of the spreading ridge

beneath the island arc. The deep earthquakes can be related to present subduction beneath the north-west Solomons and to either present north-east or past south-west subduction beneath the south-east Solomons¹³.

Ramsay also points out the lack of radiometric age dates on igneous rocks in the Solomon Islands and the fact that most of the volcanic formations are dated by stratigraphic and fossil evidence, often with poor control. Nevertheless, the early and middle Miocene is a rather well-constrained period in which the widespread deposition of limestones, calcarenites and foraminiferous marls (the Hautara, Mbetilonga and Mbonehe, and Keriata limestones on San Cristobal, Guadalcanal and Bougainville, respectively) mark a regional gap in the volcanic record^{5,6}. There are locally intercalated volcanoclastic sequences, and extensive greywackes on Choiseul and Guadalcanal, but these appear to be derived from erosion of earlier volcanics^{5,6,14}. There are no dates older than 7 Myr on igneous rocks associated with the present north-east subduction⁵. Although we noted that the apparent middle Miocene hiatus in volcanism may be evidence of a temporary cessation of subduction during the polarity reversal¹, we did not emphasize this point because the evidence from the Philippines and other areas indicates that volcanism and even double-sided subduction may occur during an arc polarity reversal.

What then is the remaining evidence for arc polarity reversal in the Solomon Islands? The term 'arc polarity reversal' was coined by Karig and Mammerickx¹⁵, who were the first to propose that this process had occurred in the Solomon Islands, primarily on the basis of studies of the New Hebrides along-strike. They assumed that all marginal basins were formed by crustal extension behind trenches, and therefore that the New Hebrides and Solomon Islands arcs formerly faced north-east. Although this assumption has since been proven incorrect^{16,17}, it is still true that the geology and geophysics of the island arcs along-strike from the central Solomons provide the least controversial evidence for arc polarity reversal. Petrochemical, sedimentological, palaeomagnetic and radiometric age data from the New Hebrides and Fiji all confirm a north-east-facing Vitiaz arc in the late Oligocene-early Miocene¹⁸⁻²¹. Vitiaz arc volcanism ceased in the late-early Miocene, the area was rifted in the middle Miocene, and following arc polarity reversal at ~10 Myr BP, a new arc was built, beginning at 7 Myr BP¹⁸⁻²¹. The Vitiaz trench and adjacent north-east edge of the Fiji Plateau still preserve the classical trench/fore-arc morphology/structure of the former north-east-facing arc²²; the same is true of the Kilinailau-Manus trench and the remnant forearcs north and east of Bougainville, New Ireland and Manus, on the other side of the

central Solomon Islands^{23,24}. Therefore, although some arguments used by early authors^{10,15} in favour of arc reversal have since been disproven, reversal of the island arcs adjacent to the central Solomons remains well documented by both island geology and marine geophysical evidence. An independent mid-Tertiary evolution of the central Solomons on the Pacific Plate would require over 1,000 km of differential movement with respect to the surrounding arcs with which they have long been associated⁶.

Given this context, we reaffirm our previous conclusion that the two juxtaposed Wadati-Benioff zones of opposite polarity provide direct seismic evidence of a reversal in subduction polarity at the Solomons island arc¹. Furthermore, although intermediate-depth seismicity on the south-dipping remnant subduction zone is only observed adjacent to the young Woodlark Basin, significant shallow seismicity is associated with this feature to the north-west^{1,25}. Finally, the location of recent volcanism on Savo, 100-150 km above the relic slab, surely implies some genetic relation between the two.

WHAT IMPACT ARE NEW BIOTECHNOLOGY TECHNIQUES HAVING ON MEDICINE WORLDWIDE TODAY?

Come to Nature's 7th International Conference in London on Molecular Biology in Medicine 1986 for all the up to date facts — and a look into the near future.

NEW TECHNOLOGY
in
BIOTECHNOLOGY

MOLECULAR BIOLOGY IN MEDICINE
a survey of its achievements and its potential
JUNE 18-20 1986 — LONDON

It is clear that the modern techniques of biotechnology are set to have a major impact on medicine. Over the next few years many new opportunities will emerge. This important conference will provide a wide-ranging survey of the most recent research in the fast changing field of molecular biology in medicine, and a look into the future. If you want an opportunity to see and hear for yourself what leading exponents have achieved in recent years — and to learn what new opportunities are on the horizon, come and join us. You'll find a booking form below.

JUST SOME OF THE NEW OPPORTUNITIES YOU CAN FIND OUT ABOUT FIRST HAND AT NATURE'S 7TH INTERNATIONAL CONFERENCE.

DIAGNOSTICS

Monoclonal antibodies to speed up and simplify laborious tests.

- engineered antibodies to provide further sophistication.
- gene probes to allow the detection of mutations that are linked to cancer.

THERAPEUTICS

the discovery of new families of proteins and peptides with potential clinical value.

- the means to engineer proteins so as to improve their therapeutic value.
- the use of monoclonal antibodies to target drugs to tissues.

PREVENTION

- the first potential vaccines against several infectious diseases, such as malaria.
- the refinement of existing vaccines.
- the detection of genetic defects with sufficient confidence and speed to prevent or limit their damage.

AMONG THE LIST OF TOP CALIBRE INTERNATIONAL SPEAKERS WILL BE

G. Schild, National Institute for Biological Standards and Control, UK
A. Capron, Institut Pasteur, Lille, France
S. Gillis, Immunex, US
M. Neuberger, LMB, Cambridge, UK
L. Montagnier, Institut Pasteur, France
K. Sikora, Ludwig Institute, Cambridge, UK
R. Gerety, Merck Sharp & Dohme, US
T. Waldmann, NIH, US
R. Baldwin, Nottingham, UK
E. Tuddenham, Royal Free Hospital, UK
D. Weatherall, Oxford, UK
W.F. Anderson, NIH, US

OUR THREE DAY PROGRAMME ENABLES YOU TO ASSESS IMPORTANT NEW BIOTECHNOLOGY TECHNIQUES IN MEDICINE. MEET INTERNATIONAL RESEARCH SPECIALISTS, AND DISCUSS WHAT YOU LEARN WITH NEW CONTACTS FROM AROUND THE WORLD.

JOIN US AT NATURE'S 7TH INTERNATIONAL CONFERENCE, TO BE HELD AT THE LONDON WEST HOTEL, JUNE 18-20 1986.

REGISTER NOW TO ENSURE YOUR PLACE — SPACE IS LIMITED. The **CONFERENCE FEE** is just £189 plus VAT for the three days of the conference. This includes entrance to all sessions, mid-morning coffee, afternoon tea and reading material. Group discounts are available on application to Janine Slipman, Macmillan Conferences and Exhibitions, 4 Little Essex Street, London WC2R 3LF, UK, Telephone (01) 836 6633.

Book before January 31st and we'll send you Nature's 1986 calendar FREE!

ACCOMMODATION has been reserved in the London West Hotel for conference participants. A booking form will be sent to you as soon as we receive your registration.

TECHNICAL SEMINARS and **POSTER SESSIONS** will be held each day.

HYBRITECH MONOCLONAL ANTIBODIES: STRAIGHT TO THE POINT.

Monoclonal antibodies are inherently pure. Inherently precise. Inherently specific. However, only genuine understanding and mastery of monoclonal antibodies can make these naturally superior diagnostic agents even better.

Hybritech is the world's leading specialist in monoclonal antibody technology. This leadership is reflected in our growing number of cost-effective, easy-to-run TANDEM clinical assays. They offer:

- Solid phase ImmunoMetric Assays (IEMA, IRMA) incorporating two carefully selected, distinct monoclonal antibodies; thus, cross-reactions are virtually eliminated.
- Outstanding lot-to-lot consistency.

- A one step procedure only one incubation step only one washing step.

TANDEM clinical assays are now available for: JGE, PAP, HGH, FER, PROLACTIN, TSH, HCG, CKMB, CEA, AFP.

Hybritech®

Leading the Monoclonal Antibody Revolution

Reader Service No. 48

The immunology industry

The wide range of monoclonal antibodies now available includes murine antibody to human calcitonin and antibodies to cytokeratin proteins.

• Becton Dickinson's monoclonal antibody Anti-Leu 12 (clone 497) is a B-cell marker for researchers studying B cells in blood or tissue section. This antibody recognizes a unique antigen present on all B cells as defined by the presence of kappa or lambda light chains. Anti-Leu 12 has not been found to react with normal T cells or concanavalin A-stimulated T cells, or granulocytes and has only marginal reactivity with monocytes and tissue macrophage. The reagent is available in a purified form or with a fluorescein conjugate and is supplied in a liquid ready-to-use solution with a long life at 4°C.

Reader Service No. 100.

• Preparative FPLC 100 and 300 ml Monobead columns are now available from Pharmacia. The IFPLC-10µ system uses new P-6000 pumps for increased high performance throughout. Designed for the separation of biological molecules, FPLC columns are widely used for the purification of monoclonal antibodies, products from recombinant DNA technology and other biologicals.

Reader Service No. 101.

Pharmacia's chromatography system, suitable for purification of monoclonals.

• A new series of Vectastain avidin-biotin complex (ABC) kits, with alkaline phosphatase (AP) as the marker, are now available in the UK for immunohistochemical staining tests. Based on the principal of the pre-formed avidin/biotinylated enzyme complex, the system is recommended in situations where high sensitivity is a prerequisite or when a high level of endogenous peroxidase activity precludes the use of the peroxidase-based ABC system. These kits can also be employed in double labelling techniques with other Vectastain ABC systems — peroxidase or glucose oxidase — and for enzyme immunoassays and nitrocellulose techniques. Following the same format as other Vectastain kits, the ABC-AP kit contains blocking serum, biotinylated secondary

These notes are based on information provided by the manufacturers. To obtain further details about these products use the reader service card bound inside the journal.

antibody, avidin DH and biotinylated alkaline phosphatase H. For convenience, a standard ABC-AP kit (with only avidin DH and biotinylated alkaline phosphatase H) is also available. Adjunctive reagents include three substrate kits, which offer a choice of three coloured precipitates: blue, black or Vector Red — a bright red permanently mountable colour.

Reader Service No. 102.

The Vector alkaline phosphatase staining system.

• The Clontech Laboratories line of cDNA libraries has been expanded to include lambda gt 11 cDNA libraries from the following tissues: human brain, human fetal liver, human lung, human neuroblastoma, bovine adrenal, bovine retina and rat lens. A genomic library from human leukocyte is also available in EMBL-3. Custom cDNA library construction is also available.

Reader Service No. 103.

• The Litton Bionetics range includes monoclonal antibodies directed against murine major histocompatibility complex antigens (H-2, Ia) from 26 cell lines. These antibodies recognize H-2 and Ia specificities coded for by genes of several haplotypes. The product is of three types — supernatant, clarified ascites or purified immunoglobulins — and serological specificity is assured by performing a complement-mediated, dye-exclusion cytotoxic assay of each product, using a panel of eight strains of mice representing non-recombinant and recombinant H-2 haplotypes. Rabbit serum screened for low toxicity to mouse splenocytes is used as the source of complement. Litton's products are available through Universal Biologicals in the UK.

Reader Service No. 104.

• Kirkegaard & Perry Laboratories now produce enzyme immunoassay kits for the detection of mouse monoclonal antibodies. The Hybri-Clonal EIA screens hybridoma cultures for clones that produce antibodies of desired specificity. The kit contains peroxidase labelled affinity purified antibody and all the reagents for 400 tests. Hybri-Clonal kits enable the

selection of clones producing antibodies of either IgM or IgG class and/or both simultaneously.

Reader Service No. 105.

• LKB Instruments has produced a 20-page technical description of their 1.2 and 4 detector automatic gamma counter, the model 1272 CliniGamma. Cutaway drawings show how the shielded detectors in this multiple-detector RIA counter are positioned. Other sections deal with the continuous automatic calibration of all detectors, standardization of detector efficiencies, backgrounds and inter-detector crosstalk, plus chi square testing for detector repeatability. Sample racks, containers, variation in sample volumes, compatibility with automatic pipettors and centrifuges, and a positive sample ID system are all detailed. Programming and control of the CliniGamma receives over five pages of explanation. Data reduction methods given are: log-logit regression and the sophisticated cubic spline function for curve fitting plus various emulations of manual point-to-point graphing, a thyroid group for T₄/FTI/free T₄, and a hepatitis screening group of five methods, all on- or off-line.

Reader Service No. 106.

Tissue culture and monoclonal production are applications requiring pure water, as produced by the Millipore Milli-Q.

• The Millipore Milli-Q Water System provides organic-free (less than 20 parts per 10⁹ TOC) or pyrogen-free 18-megohm water for critical applications including tissue culture and monoclonal antibody production. The Milli-Q system produces just as much water as needed, when needed, at up to 1.5 litres a minute. This eliminates the need for storage and the consequent degrading of water quality. Unlike stills which require regular time-consuming scale removal, Milli-Q cartridges can be changed in minutes without tools. In addition, Milli-Q Ultrapure cartridge kits provide all the replacement cartridges needed under one catalogue number.

Reader Service No. 107.

Cardiac diagnosis by Centocor.

• Centocor Inc. has introduced a
radiolabelled monoclonal antibody for
rapid differentiation of cardiac necrosis
and ischaemia following myocardial in-
farction. Called Myoscint, the antibody is
selective for the heavy chain of the in-
tracellular cardiac muscle component
myosin which is exposed when the cell
membrane ruptures during a heart attack.
The indium-III labelled Myoscint there-
fore binds exclusively to necrotic cardiac
cells and images of these are obtained us-
ing a conventional gamma camera.

Reader Service No. 108.

• Serotec of Bicester, Oxfordshire, has
announced an extended range of con-
jugated monoclonal antibodies. The com-
pany developed a method of conjugation
which makes it possible to add labels to
most antibodies in the Serotec range of
monoclonal products. These labels in-
clude FITC, TRITC, peroxidase and alka-
line phosphatase. The conjugates are sup-
plied in 1 ml vials, with a concentration of
bound antibody of 1 mg ml⁻¹.

Reader Service No. 109.

• Hybritech's list of monoclonal anti-
bodies has been expanded to include
murine monoclonal antibody to human
calcitonin, used in studies of certain carci-
nomas and bone disease, and monoclonal
antibody to bombesin, a tetradeca-
peptide, present in mammalian tissues
including brain and gut. Also available
now is pooled AE1 and AE3 monoclonal
antibodies to human epithelial keratin,
which should prove useful for the positive
identification of normal and abnormal
epithelial cells in tissue sections and cul-
ture, and for distinguishing carcinomas
from non-carcinomas. And monoclonal
antibodies to hepatitis B surface antigen
and subtypes as, adw and ay are also avail-
able, which should help in a new and im-
proved methods for hepatitis screening
and diagnosis.

Reader Service No. 110.

• A new HistScan monoclonal detector
kit for the localization of both mouse and
rat monoclonal antibodies following their
reaction with tissue antigens is now avail-
able from Biomed. This monoclonal de-
tector kit is designed to simplify the tissue
immunostaining technique using mono-
clonal antibodies specific for tissue-
associated antigens. It is based on the new
avidin biotin complex technology kits con-
tain all reagents needed to detect mono-
clonal antibodies in 150 tissue sections.
Also contained in each kit are haematoxy-
lin counter-staining reagent, concentrated
chromogen reagents and pertinent block-
ing solutions to minimize nonspecific
staining. The reagents forming the kit are
supplied in a ready-to-use form together
with a step-by-step procedure outline and
other technical information. When stored
at 4°C, the kit has a shelf life of one year.

Reader Service No. 111.

• A new edition of the Boehringer Man-
nheim Biochemicals Catalogue is now
available. It lists over 1,500 products in-
cluding products for molecular biology,
immunology, cell culture and general
biochemistry. This revised edition is de-
signed to be easy to use. The main section
is an alphabetical product listing which
contains all the pertinent information on
product specifications. In addition, there
are quick reference listings for molecular
products and for immunology and cell-
culture products, extensive cross refer-
ences and indexes organized both
alphabetically and by product group. For
a free copy contact Boehringer Mannheim
at 7941 Castleway Drive, P.O. Box 50816,

Indianapolis, Indiana 46250.

Tago's new reagents for immunohistology.

• Tago's series of horseradish
peroxidase-antiperoxidase (PAP) soluble
complexes has been specially prepared for
use in immunohistological staining and
quantitative enzyme immunoassays.
These convenient, step-saving reagents
provide a more sensitive assay than
fluorochrome-conjugated antibodies and
a higher signal than standard peroxidase-
conjugated antibody. They also may be
used with fixed tissues as well as with
frozen sections in detecting most antigens.
PAP complexes are now available for ap-
plications with goat or rabbit primary im-
munoglobulins. They are effective at
working dilutions of 1:20,000 for ELISA
and up to 1:200 for tissue staining proce-
dures. PAP complexes can be linked with
primary antibodies through second anti-
bodies to goat or rabbit IgG.

Reader Service No. 113.

• Dako Corporation is introducing con-
trol slides in 10-packs — one stained for
reference and nine unstained slides. These
ready-prepared controls can reduce time
spent searching for, acquiring and proces-
sing tissue. Hard-to-obtain controls for
antigens such as α -fetoprotein, papillo-
mavirus, herpes simplex virus and nearly
20 other immunohistochemical markers
are included in this new product line. Each
slide is ready for immediate use. Each kit
includes recommended step-by-step proce-
dure and a technical staining description.

• Adding to its range of arachidonic acid
metabolites, Seragen has introduced a
leukotriene B₄ ³H RIA kit. With its highly
specific sensitivity, the researcher can
achieve accurate results with samples as
low as 10 pg per 100 μ l in a simple 2-hour
room temperature assay. The antiserum
has low cross-reaction with other leuko-
trienes and HETEs so that no HPLC sam-
ple separation is necessary.

Reader Service No. 115.

• Coulter Immunology has announced
the availability of three exclusive leuko-
cyte monoclonal antibodies. The new
Coulter Clone monoclonal antibodies —
2H4-RD1, 4B4-RD1 and Ta1-RD1 — will
enable investigators to identify functional
T4 subsets which play precise roles in the
onset of autoimmune and immune de-
ficiency diseases. Anti-2H4-RD1 defines
the functionally unique T4+ subset, sup-
pressor inducer, which falls dramatically
in certain patients with the onset of syste-
mic lupus erythematosus. 4B4-RD1 de-
fines the T4+ cell subset, helper inducer,
and may be the key parameter for the

An international diagnostic company,

YOUR RESEARCH IS HIGH CALIBER.

THE RIGHT SOFTWARE WILL KEEP IT THAT WAY.

That's why leading biotechnology companies have been using IntelliGenetics molecular biology programs for years. It's also a reason why the NIH-funded Bionet™ National Computer Resource for Molecular Biology chose IntelliGenetics software for the core of its program library.

Powerful programs that require no computer experience.

The software is an integrated package that enables you to design experiments and predict the results, manage and assemble sequencing data, and analyze DNA and protein sequences. You can search the major databases and perform sequence comparisons using three different algorithms. This ensures that no one knows more about your sequence than you do.

IntelliGenetics programs are fast.

The AIDS virus was sequenced with the GEL program because speed was critical. BIOTECHNOLOGY SOFTWARE reported that the software "usually responds faster than the user can read." That's one reason the software is designed to operate only on powerful computers. You can license the programs for the VAX or the SUN Workstation or run them on a timesharing basis on IntelliGenetics' mainframe.

Comprehensive support for both the novice and the expert.

Training seminars, documentation, and troubleshooting by a trained staff of molecular biologists ensure that you can get help when you need it. IntelliGenetics keeps working with you *after* you buy its software.

• A new Pentex antigen/antibody enhancement medium and antisera diluent called Mod-U-Cyte is now available for research and manufacturing use at two protein concentrations, 6% and 20%. The suppliers, Miles Scientific, say its advantages include: Rh and certain other rare antibodies are more reactive at both pre- and post-antiglobulin test phases when compared to conventional, highly polymerized and low ionic strength bovine albumin solutions; certain weak clinically significant IgM antibodies can be detected without using proteolytic enzyme-premodified red blood cells; and with Mod-U-Cyte as a blood grouping and typing antisera diluent, most titres are extended two to 16 times when compared to solutions using bovine albumin as a diluent. Mod-U-Cyte may enhance availability of cell surface antigen sites.

Reader Service No. 117.

• Jackson ImmunoResearch has introduced a new line of over 200 biotinylated antibodies which have a 13-atom spacer between biotin and the antibody. This results in a significant increase in sensitivity. The spacer appears to extend the biotin moiety far enough from the antibody surface to make it more accessible to biotin-binding sites on streptavidin and avidin, especially when they are labelled with high molecular weight enzymes. It appears that either more enzyme-avidin conjugate can be spatially accommodated on the antibody surface or perhaps the extended biotin has better access to its

binding sites which are sterically recessed from the surface of the enzyme-covered avidin. The new products, designated Biotin-SP to indicate biotin with a spacer, will be available on all biotinylated AffiniPure antibodies and ChromPure proteins. Biotin-SP enzymes containing the same 13-atom spacer will also be available to form avidin-biotin-enzyme complexes for use in histochemical/cytochemical procedures requiring ultra-high sensitivity. Fluorophore-labelled and enzyme-labelled streptavidin and avidin are available for use with Biotin-SP-AffiniPure antibodies and Biotin-SP-ChromPure proteins.

Reader Service No. 118.

• Celltech Limited produces a range of immunoprocessing reagents based on the company's expertise in large scale monoclonal antibody production. In September 1985 Celltech extended its range of monoclonal-antibody-based immunoprocessing reagents with the introduction of Resolute IL-2 and IL-2 IRMA, for the purification and assay, respectively, of human interleukin-2. The reagent gives a high purity of interleukin-2 in a single-step chromatographic process, and is a reliable, rapid and reproducible alternative to the more traditional 'bioassay' in-2. Celltech also supplies monoclonals for ABO blood typing.

Reader Service No. 119.

• Euroclone is a new European company specializing in the contract production of mammalian secreted products such as monoclonal antibodies, human growth hormone and tissue plasminogen activator. The company is interested in both small and large scale production orders. Production is based on the computerized facility, Acusyst-P. This system, manufactured by Endotronics Inc., uses hollow-fibre technology in combination with a dosage of cell media. For each customer all the manufacturing conditions are very well defined and reproducible. The cost per gram of secreted product should be significantly lower than the usual level. Euroclone is a joint venture of Dalton-Waalwijk, of the Netherlands, and a well-known European immunology institute.

Reader Service No. 120.

• BioTope, Inc. of Bellevue, Washington has announced two new immunoassay kits for the cancer research market. These assay kits are claimed to be the first commercially available immunoassays for detecting and measuring human transforming growth factor alpha (hTGF- α) and human epidermal growth factor (hEGF). The kits detect these growth factors in urine. Based on BioTope's proprietary microassay technology, BioMAT, the kits combine speed, economy and reproducibility. BioMAT should find numerous applications in immunoassays, receptor assays and DNA probe assays.

Reader Service No. 121.

• A radioimmunoassay kit suitable for the determination of the level of atrial

natriuretic polypeptide (ANP) in unextracted plasma samples has been developed by Research & Diagnostic Antibodies. ANP is the recently described heart hormone involved in the regulation of blood pressure due to its hypotensive, diuretic, and natriuretic actions. The assay can accurately determine the quantity of ANP in 0.05 ml to 0.10 ml of unextracted normal plasma. The assay has a minimum sensitivity of 2 pg ANP per tube.

Reader Service No. 122.

• The Ribi Adjuvant System (RAS) from Ribi ImmunoChem Research, Inc. is an easy-to-prepare adjuvant system intended as an alternative to the classical Freund's water-in-oil emulsion. RAS is a stable oil-in-water emulsion. Adjuvanticity is improved when the adjuvant is incorporated together with the antigen into the oil phase, rather than incorporating the antigen into the aqueous phase. The mixture is then dispersed in a large volume of saline containing microscopic oil droplets. This makes it possible to have a reduced oil concentration (2% instead of 50%), thereby reducing emulsion viscosity. In RAS the tubercle bacilli contained in complete Freund's adjuvant are replaced by trehalose dimycolate, a highly purified adjuvant. Monophosphoryl lipid A (detoxified endotoxin), *Salmonella typhimurium* mitogen or cell wall skeleton can be added to further enhance immune response.

Reader Service No. 123.

• Seven monoclonal antibodies specific for cytokeratin intermediate filament proteins are now available from Amersham International. This range includes antibodies for use with formalin fixed paraffin embedded material, having an expected application in the sub-typing of normal and pathological epithelia. Also included are antibodies recommended for use with unfixed frozen material. All these antibodies can be used for immunofluorescence staining of cultured cells and 'Western' blot analysis of cytokeratin proteins.

Reader Service No. 139.

• Gibco/BRL's range of products for immunology consists of monoclonal antibodies, hybridoma screening kits and reagents for immunoprecipitation and purification of immunoglobulins. Products for immunodetection based on streptavidin-biotin technology include biotinylated secondary antibodies, streptavidin conjugates and enzyme substrates designed for use in the detection of target antigens by various immunoassay procedures such as ELISA, immunoblotting and immunocytochemistry. For immunoprecipitation BRL offers streptavidin agarose, protein A agarose and immunoprecipitin. For further information on all Gibco/BRL streptavidin-related products use the reader service code to send for a brochure illustrating the applications of streptavidin in the detection of protein, cells and DNA.

Reader Service No. 124.

- Bio-Rad has produced a new publication giving details of a range of high-quality instruments, systems and reagents for purifying and characterizing monoclonal antibodies. The booklet provides information on techniques for purifying antigen by gel electrophoresis and chromatography, screening hybridomas and characterizing hybridoma-secreted immunoglobulins. In addition, there are descriptions of HPLC purification systems and applications for monoclonal antibodies. *Reader Service No. 125.*
- ICN Biochemicals announces the availability of Lipid A, a biologically and immunologically active toxic component of lipopolysaccharides. It has been isolated separately from the serologically specific polysaccharide fraction. Lipid A is known to elicit endotoxic responses, and the availability of this purified form should make it easier to study those responses without the problem of interference from the polysaccharide fraction of lipopolysaccharide. *Reader Service No. 126.*
- Eight new affinity purified antibodies (APAs) to human IgG (Fc), human IgG (Fab) and their corresponding conjugates (FITC, peroxidase, alkaline phosphatase) have been added to Bio-Yeda's range. Products in this series comprise APA to mouse IgG (Fc) and mouse IgG (Fab) and conjugates, and APA to rabbit IgG (H+L). Bio-Yeda APAs and conjugates are purified from goat serum by affinity chromatography with immobilized antigens. At least 95 per cent of the eluted antibodies are active as determined by use of quantitative immunoprecipitation analyses. Because of minimal interspecies crossreactivities to mouse and rat serum proteins, the APAs to human Fab and Fc and their respective conjugates may be used for screening of human monoclonal antibodies produced by hybridoma cells grown *in vitro*. The affinity purified anti-human Fab reagents offer the advantage of increased sensitivity for all the possible human immunoglobulin isotypes (IgG all subclasses, IgA, IgM, IgD, IgE) in biological fluids of tissues in normal or pathological situations. APAs to human Fc and respective conjugates detect specifically human IgG with its four subclasses IgG₁, IgG₂, IgG₃ and IgG₄. The conjugates of these anti-human immunoglobulin reagents are very effective as secondary reagents in ELISA, immunoblotting and immunohistology. *Reader Service No. 127.*
- RIA (UK) Ltd has introduced the Histoclone range of immunohistochemistry kits, based on a series of eight monoclonal antibodies. Designed for the specific identification of human antigens, the kits use routinely fixed, paraffin-embedded tissue samples, or frozen tissue sections. The monoclonal antibodies have been raised against eight diagnostically crucial antigens: luteinizing hormone, human chorionic gonadotropin, growth hor-

none, thyroid stimulating hormone, prolactin, alpha-fetoprotein, carcinoembryonic antigen and human B cells/Ia-like. *Reader Service No. 128.*

- New from Biotest-Serum-Institut GmbH is a monoclonal antibody against interleukin-2 receptor (Clonab IL-2 R) which detects human activated proliferating T cells. Extremely high purity allows 10 functional tests and more than 1,000 immunofluorescence tests from 1 ml of lyophilized preparation (1 µg of highly purified antibody). *Reader Service No. 129.*

- Becton Dickinson has introduced a new second-antibody for immunofluorescence staining. The monoclonal rat anti-mouse kappa is conjugated to phycoerythrin as a bright second-step reagent for indirect analysis. It is significantly brighter than a FITC conjugated second-step, when used in flow cytometry or microscopy. Anti-mouse kappa phycoerythrin detects low-density antigens where resolution between stained and unstained cells is critical. *Reader Service No. 130.*

- Costar's new Transtar-96 is a portable 96-well liquid handling system with an adjustable volume range of 25–200 µl. The system is completely autoclavable for use in a sterile environment. The heart of the system is a polystyrene radiation-sterilized disposable unit with 96 pipette tips moulded in one piece, covered by a medical-grade silicone rubber membrane. Applications include changing cell culture medium and liquid transfer for assays, for instance in screening of monoclonal antibodies. The 96-well microplate with low evaporation lid minimizes overall evaporation and eliminates "edge effect". *Reader Service No. 131.*

- Metachem Diagnostics' range of specialist antisera for immunocytochemistry now includes antisera to corticotropin releasing factor, growth hormone releasing factor, PHM-27, calcitonin gene related peptide, neuropeptide Y, galanin and peptide YY. The antisera are lyophilized and sealed under nitrogen. After reconstitution the antiserum is ready for use for either PAP or FITC techniques. Supplied with each antiserum is a data sheet with recommended immunohistochemical protocol. *Reader Service No. 132.*

- Cambridge Research Biochemicals have extended their range of peptide antisera to include polyclonal antisera raised to human neurone specific enolase for radioimmunoassay. Pure human neurone-specific enolase is also available. *Reader Service No. 133.*

- The *ras* family of oncogenes are the oncogenes most commonly found in human tumours and have been associated with bladder, lung and colon carcinomas, and various leukaemias. Because the proteins produced from *ras* oncogenes have molecular weights of 21,000, they are referred to as "p21" proteins. The Cetus *ras*

oncogene product monoclonal antibody can be used for experiments designed to explore *ras* oncogene expression in tumours and mutant-specific polyclonal antibodies can be used to detect *ras* mutations, resulting in single amino acid changes in p21. These single amino acid mutations activate the *ras* proto-oncogene to the oncogene form. Rabbit polyclonal antibodies capable of detecting oncogene forms of p21 with serine, valine, arginine or aspartate at position 12, and anti-p21 pan-reactive monoclonal and polyclonal antibodies were introduced at the *Nature* Conference in San Francisco last month. *Reader Service No. 134.*

- The latest Immunochemical Products catalogue from Zymed includes a long list of affinity purified antibodies to mouse, human and rat immunoglobulins. Each antibody is characterized according to its reactivity to a specific class of immunoglobulins and cross-species reactivity. The streptavidin/biotin system is of particular interest to those who need to enhance the signal for enzyme immunoassay, histochemical and cytochemical staining whilst retaining negligible background. Monoclonal antibodies are also listed as are recommended methods used in immunology. *Reader Service No. 135.*

- Organon Teknika has introduced what is claimed to be the first non-isotopic immunoassay for FSH and LH in serum or plasma. Both tests, FSH-Nostika and LH-Nostika, are based on the sandwich principle for the detection of physiological values of the respective hormones. Incubations are at room temperature, and results are available on the same day (total incubation of 4½ hours). The system gives good reproducibility and has the same sensitivity as radioimmunoassays. *Reader Service No. 136.*

- The new disposable affinity columns from Biological Consultancy Services (BCS) make it possible to purify mouse or human IgG, IgM, IgA from serum, tissue culture fluid or ascites in one step. Each column can be used several hundred times: thus they will purify immunoglobulin from as little as 1 ml fluid or as much as several litres. Immunoglobulin can be purified to >99% purity in one step. There is no need to concentrate the starting fluid or to partially purify by ion-exchange or molecular size chromatography. *Reader Service No. 137.*

- Labsystems' Uniskan range of photometers includes the new Uniskan II, designed for use in absorbent and turbidimetric measurements typical of enzyme immunoassay and microbiological work. Uniskan's optics are based on vertical photometry which eliminates the adverse effects of layering, evaporation and other sources of error. The life of the light source has been extended to a quarter of a million measurements by means of pulsing the beam. *Reader Service No. 138.*

Last high-noon for UNESCO

The British government seems determined to pull out of UNESCO. Here is a last-minute plea that it should change its mind. But UNESCO's problems will remain.

THE fine Corbusier building in Paris inhabited by UNESCO (United Nations Educational, Scientific and Cultural Organization) is not noticeably upset by the prospect that the United Kingdom may cease to be a member at the end of the year (three weeks from now). After all, the least successful of the UN's agencies has just returned from a conference at Sofia at which it seemed to make concessions to its critics, and gained the impression that some of them had been silenced. After the departure of the United States (responsible for 30 per cent of the 1984 budget), which seems to have left most things unchanged, how can the defection of the United Kingdom (with its mere 7 per cent) shake the edifice substantially? The simple answer is that the present time is a lull before a storm. UNESCO is going to have to change, not merely because of the complaints against it but from necessity. The strongest argument why the British government should not now pull out is that, if it stays, it has a good chance of being showered with the plaudits that will be showered on the reformers.

A still better reason for staying in is that there is much to do. UNESCO's errors are mostly errors of commission. It has tilted at impossible windmills, such as the objective of bringing about a new world information order (a device for making sure that governments are never offended by what their newspapers publish). Yet UNESCO has also done good works, it remains, for example, the only substantial source of support for the International Council of Scientific Unions. By any standards, a programme composed of such a mixture of the impossibly utopian and the practically utilitarian cannot but be endearing. The challenge, and the task that will remain even if Britain leaves, is to hammer this programme into shape.

For all its outward toughness about UNESCO, even the British government has not faced the central error in UNESCO's way of doing business, the generally accepted belief that the organization is meant to play a decisive part in the development of developing countries. Mr Timothy Raison, the British Foreign Office minister responsible for overseas aid (and for UNESCO), who has been sympathetically hard-headed on British membership over the past year, fell into the familiar trap in his speech during the House of Commons debate on UNESCO last month. Get those civil servants out of Paris, and into the Field, is the cry. The reality is that there are half a dozen other UN agencies whose terms of reference enjoin them explicitly to assist development, and whose budgets are more nearly commensurate with the task. A large part of UNESCO's difficulty over the past few years is that the majority of its members (developing countries) have insisted that it should become another aid agency, and that its paymasters (governments like the British) have weakly fallen in with the proposal.

By all accounts, the same error was repeated at last week's meeting of the British National Commission for UNESCO, the representative body of the great and the good which the government feels compelled to consult (but not compelled to listen to) at times like these. Most voices spoke for UNESCO's further transformation into a lowly version of, say, the Rockefeller Foundation that would remain hamstrung by its constitution, and by the need to deal equally with all of its constituents. The need for development, as this year's experience in most of Africa has all too plainly shown, is too urgent to be safely

neglected for much longer. But that, unfortunately, does not imply that UNESCO, already driven far off course, should be thrown ineffectually into the battle. The scale of its operations is simply too small to make much difference. But equally, it is not necessary that UNESCO should continue indefinitely to be the chief source of support for worthy organizations such as the International Council of Scientific Unions, which could (and should) keep itself alive by means of contributions from its members. UNESCO needs most of all to discover what it is for, and to pursue those goals wholeheartedly.

What might be done? It is not so long since UNESCO claimed to be an important influence in the teaching of science and technology in schools. It retains some influence in that field, spending modest sums on useful good works such as the design and manufacture of school science equipment, notably through its centre at the University of Delhi. But UNESCO has never had the nous to appreciate the generality of the difficulties of science teaching, the simple truth that rich countries such as the United States are as perplexed as the poorest among the UN's members. That is a field that a reformed UNESCO would plough. And why not extend the same principles both to other parts of the curriculum of the young?

In short, UNESCO's programmes should be devised to span problems within its terms of reference (education, science and culture) which are common to its members, not the exclusive concern of the poorest among them (or of any other class). Among present programmes, that to catalogue and, if possible, to preserve sites of archaeological or cultural importance to the international community is a good model for what might be done (if a poor model for administration). In the past, UNESCO has similarly helped to reach compromises between the rich and poor countries on questions such as copyright, where the trick has been to reconcile conflicting interests. There are many other issues of this kind that need attention, but which will not be attended to if too many UNESCO members quit.

That is the prize the British government should stay to help to achieve. There are few who would not accept its view that UNESCO as it stands is a badly administered can of worms which, by its reputation, does more harm than good to the cause of international cooperation. The obvious difficulty is that, if UNESCO should now collapse, it would not be reinvented within the lifetime of anybody now alive. Yet the tasks that cry out to be tackled are too important to wait that long, while the shocks to UNESCO of the past two years provide an opportunity that will not soon recur. □

Changing of the guard

The Royal Society has a new president, but it may also need a new policy.

SIR Andrew Huxley, who retired last weekend as president of the Royal Society, has predictably done a splendid job during the past five years. Undemonstratively temperamental, almost the opposite of a power-seeker, his capacity (and liking) for intellectual work has enabled Britain's best known society to enhance its reputation for giving advice that cannot be ignored. During his spell in office, Sir Andrew has also emerged (again

predictably) as a courageous president: he has told off his opposite number in Moscow for the Soviet treatment of Sakharov and, more recently (see p.399), the organizers of next year's archaeological congress at Southampton for their indifference to the principles of freedom in science. That the administration of the society has been refreshingly improved during his tenure of office is an unexpected bonus. He is affectionately forgiven for his intervention on behalf of the British Museum (Natural History) — which should find itself a better name — in its dispute with *Nature* over the public presentation of evolution (see *Nature* 291, 373; 1981).

Huxley's successor, Sir George Porter, will almost certainly do as well. His record in research is similarly distinguished (with a Nobel Prize, while they last, a qualification for the job among other things), but he also has a foot in another camp, the popularization of science. Especially as director of the Royal Institution (Humphry Davy's home for Michael Faraday), Porter has done more than most working professionals to make sure that the world at large should have a better understanding of why science is important. It is no surprise that he should have said at the weekend that, for the next two or three years, the public understanding of science will be one of the Royal Society's preoccupations. There is a great deal of enlightenment to be effected. Everybody will hope that the new president can work a little wonder.

The obvious difficulty is that this is only part of the battle that needs to be fought. Logic would suggest that if the British electorate were better informed about the excitement of what happens in laboratories, it would sense the potential economic as well as cultural value of what is called research and instruct their elected representatives accordingly; and the consequence of that, the argument goes, is that British governments would no longer be able to deal with budgets for research as if they were any old kind of public spending. Unfortunately, in this as in other fields, logic is an inadequate guarantor of good sense, and is in any case slow to work its way through the electoral system. And although most British scientists will now say that their troubles stem from the cuts which there have been in their budgets, that is only half the truth. It matters at least as much that the system of research organizations spending what funds there are has been slow to accommodate itself to the changing environment. The simple consequence has been that potentially creative people have too often allowed themselves to be persuaded that they cannot hope to accomplish much.

In these depressing circumstances, the most urgent need of the British research enterprise is for leadership. It will help a great deal if researchers discover the Royal Society to be hard at work instructing people at large that science is a worthwhile enterprise, but there is more that needs doing. In particular, there is a need that some organization that stands for science, but which also understands the government's need to spend less, should more openly function as an informed critic of mismanagement of the kind that has marked the past few years. Who better than the Royal Society?

There are three stock explanations, one of which is that the Royal Society depends on public funds for most of its support, another that the society delivers its opinions confidentially, to those (in the government and elsewhere) who must act on them and, third, that a society composed of individuals elected for their academic distinction cannot be expected to have what might be called a corporate view. There is something in each of these arguments. It is a particular embarrassment that the Royal Society should both be dependent on the Advisory Board for the Research Councils for its own funds and an *ex officio* member of the same committee, no doubt because of the potential value of its candour. The view that the giving of advice through private channels inhibits public criticism is less cogent. And while it would probably be impossible to win an agreed view by the Royal Society's members on, say, the best way to finance the British Broadcasting Corporation or even the wisdom of replacing *Polaris* by Trident submarines, there is every chance that they would unite behind a measured and public criticism of

government policy towards British science in the past five (or even fifteen) years. What seems not to be understood is the degree to which morale in the laboratories would be stiffened by the emergence of an influential monitor of the present course of black events. It is possible that Sir George Porter has just such a plan hidden behind the slogan of public understanding. Now, at least, the Royal Society has a policy unit that could be the source of the analysis needed to sustain such a role. Why not take it up? There is much to be gained and, now, not much to be lost. □

Broadcasting in chaos

The British government has encouraged a sense of being mean that now extends to the BBC.

LIKE public policy on strategic arms, public policy on broadcasting is also an issue with which the technical community must grapple. The simplest reason is simply given; without the technology, there would be no issue, so that the innovators have a continuing responsibility. The more complicated but more interesting reason is that the innovators (or the inheritors) have a proper self-interest in the use made of the technology; will it, they may ask, further our interest that there may be more discovery and innovation? Those who may be sympathetic to this notion should pay some attention to what is happening to the British Broadcasting Corporation (BBC), certainly the best broadcasting organization in the world.

The BBC is constitutionally a public corporation, legally given (by charter) the right to function as if it were a corporation (or joint-stock company, as the Victorians would have said) but also saddled with the responsibility to broadcast material that gives neither personal nor political offence. But unlike other corporations, the BBC raises the funds it needs to keep on the air by means of an annual payment by those who own television and radio sets. This arrangement, conceived of in the 1920s, when television had not been invented, and when even the ownership of a radio receiver was a privilege, persists to the embarrassment of both the BBC (which needs the money) and the British government (which must periodically sanction an increase in the licence fee as, grudgingly, it did earlier this year).

So should not the market play a more prominent part in matching public expectations of broadcasting organizations to what the broadcasters provide? Especially because it has not escaped public attention that most broadcasting organizations are financed on a commercial basis, selling part of the time for which their audiences are prepared to listen to outsiders with other messages to impart, should not the BBC also sell time to advertisers? It would be unjust to the present British government to complain that it has insisted that this question should be answered. It has merely created the climate in which the question cannot be avoided.

The outcome is a committee under Professor Alan Peacock now brooding on the future financing of the BBC. Last week, the committee organized a meeting at which people whose views are well known repeated them for a gathering of others whose views are equally well known. (There were journalists in attendance, in the gallery.) The most radical (and the best) of the free-market solutions to the government's problem about the BBC (due to Mr Peter Jay, once British ambassador in Washington) is that people should pay for what they receive from among what is broadcast as they do for telephone calls. The trouble is that that is also politically unworkable. Most voters who now say that they would prefer that the BBC should take advertising than that the licence fee should be increased might turn nasty if they thought they would have to pay by the minute not the year. Yet the BBC must somehow be taken off the backs of successive British governments, all of which have been prepared to take credit for its quality while resenting the need to approve new licence fees. Why not turn the corporation into a public foundation which, unlike the Public Broadcasting Service in the United States, would be financed by an endowment, not an annual subvention? □

Apartheid in science

Crunch still ahead for archaeology congress

THE planners of next year's World Archaeological Congress at Southampton (England) have during the past week encountered mounting but conflicting pressures over the exclusion of South African scientists. The most ominous development is the decision of the International Union of Prehistoric and Protohistoric Sciences (IUPPS) to hold a special meeting of its executive committee (in Paris on 17 January 1986) to consider the matter. Meanwhile, the presidents of the Royal Society and the British Academy have spoken out against the exclusion, but the British committee organizing the congress has reaffirmed its earlier decision to ban South Africans.

The meeting of the executive committee of IUPPS (not to be confused with the British committee responsible for the congress) could affect what happens next year in Southampton. In principle, the committee could decide to withdraw its *imprimatur* from the congress. In that case, according to Professor John Evans, the president of IUPPS who is also chairman of the British committee, it would be necessary to "consider again" the arrangements for next year's congress.

The intervention of the presidents of the Royal Society and of the British Academy first took the form of a letter to *The Times*. On 17 November, Sir Andrew Huxley and Sir Randolph Quirk, speaking for their respective academies, referred to their "profound concern" at the decision to disinvite scientists from South Africa. They said that "it is an indispensable condition of holding an international conference that *bona-fide* scholars should be admitted irrespective of nationality, domicile or politics" and went on to describe the decision not to allow South Africans as "deplorable".

Huxley and Quirk went on to say that the decision could mean that Britain would cease to be regarded by bodies such as the International Council of Scientific Unions as "a fit place in which to hold an international scientific congress". Huxley expanded on this theme in his final anniversary address to the Royal Society last Saturday (30 November).

The meeting of the British National Committee on 20 November seems to have surprised those present by the weight of opinion in favour of continuing the ban. On one account, only one of a score of members spoke in favour of rescinding the ban. There are reports of overseas scientists having withdrawn from the congress, but the numbers are said to be "only about thirty". The possibility of moving the congress to another venue had been con-

sidered, only to be discounted on the grounds of lack of time.

At Southampton, the organizers have a sense of having been misunderstood, even misrepresented. Professor Peter Ucko, the secretary of the organizing committee, says that nobody has appreciated the trouble that had been taken to ensure the attendance of genuine scientists from developing countries. In this respect, he says, there is every prospect that the congress will be a success. Moreover, it had been arranged that participants would attend as individuals, not as nominated delegates of national organizations.

But, Ucko went on to say, people do not appreciate that "you cannot now hold a conference and invite people from South Africa if you also hope that there will be people from up to thirty Third World countries". This is the reality, Ucko says that conference organizers cannot ignore.

The sequence of events leading to the

ban on South Africans, beginning towards the end of the 1984-85 academic year, is not easily reconstructed. Ucko cannot at this stage recall whether the first representations came from the students at Southampton (whose union and, in particular, debating hall, is required for the congress) or from the local branch of the Association of University Teachers. The formal decision of the Southampton City Council to withdraw financial support came relatively late, he said, although there had been informal representations earlier in the summer.

Ucko, like many others involved in the conference organization, says that people have not paid enough attention to the moral indignation of those opposed to South African participation. The University of Southampton has not considered the trouble caused by its proposed hospitality for next year's conference, and may not do so. The vice-chancellor, Mr G.R. Higginson, said earlier this week that the university had no formal status in the congress except as the provider for accommodation during the university vacation. But Mr Higginson added that he had told the organizers during the summer that he saw no alternative to their decision to ban South Africans once the opposition to their presence had become apparent.

Keyworth resigns as US science adviser

Washington

DR George A. Keyworth III, President Reagan's science adviser since 1981, announced last week that he is to resign from the position before the end of the year. Keyworth is widely credited with having successfully defended basic science even while other budgets were being cut, but also earned some unpopularity for

silence defences, which some fear could distort the pattern of financial support for basic research. But Keyworth said last week he was leaving at a time when everything was running smoothly: he was comfortable that SDI was on a firm footing and was encouraged by the general increased recognition of the importance of basic research, especially that conducted in universities.

William Carey, executive officer of the American Association for the Advancement of Science, said that Keyworth had earned a degree of access to the President that few other science advisers had achieved. He had also proven extremely effective in persuading the Office of Management and Budget to respect the importance of basic research, and had initiated important changes aimed at improving the efficiency of federal laboratories.

If Keyworth's term has been marked by generosity to basic science, his resignation comes at a time of widespread concern over the future level of support for science. Congress is considering legislation to reduce the federal budget deficit that would hit science hard, and many federal agencies have been told to expect budgets next year equal to or lower than this year's.

Keyworth is planning to establish a business with a former employee of the Central Intelligence Agency to advise companies on intelligence-gathering, where he is likely to command rather more than the \$70,000 salary he earned at the White House.

Tim Beardsley

being identified very much as a member of Keagan's team rather than as an emissary of the scientific community.

Keyworth has been a staunch supporter of President Reagan's controversial Strategic Defense Initiative (SDI) programme of research into anti-ballistic mis-

French research

Salomon speaks out (unpublished)

FRENCH technocratic centralism may have worked brilliantly for Ariane, nuclear power and high-speed trains, but it is not working, and will never work, for biotechnology, electronics and other consumer-oriented technologies. So argues Jean-Jacques Salomon, the only professor of science and technology policy in France, in a blistering — and unpublished — report now circulating at the Organisation for Economic Cooperation and Development (OECD), where Salomon was head of science for more than a decade.

Salomon's almost unrelieved criticism of French technology policy was commissioned 18 months ago by the prime minister, Laurent Fabius, in his then role of industry and research minister. Salomon submitted it to Fabius's successor, Hubert Curien, in July, but has heard nothing since. He is said to be furious that his passionate 160-page report may now simply gather dust.

The contents seem likely to guarantee that fate. For example, the report describes the creation of a grand ministry of research and technology by Jean-Pierre Chevènement as little more than "bureaucratic inflation". Scientists, writes Salomon, had much more influence over French policy in the pre-Chevènement days of the former and far smaller administration, the Délégation Générale de la Recherche Scientifique et Technique (DGRST).

The administrative consequences of Chevènement's expansion was a ministry split into several competing factions, says Salomon. This administration made only internal evaluations of its work, and rarely consulted its scientific advisers. Some advisory committees never met, according to the report, allowing bureaucrats to define programmes that were ends in themselves, not the means to innovation in the French economy.

In Salomon's report there are no scared cows, not even research spending. Basic research in France has enjoyed a 51 per cent budget rise since 1981 (without allowing for inflation), and applied programmes have seen a near doubling of spending. But according to Salomon, this attachment to a large increase in research and development spending as a fraction of gross national product has been "fetishism". (The ratio was 1.8 per cent in 1980, and 2.2 per cent now so a real increase has been achieved; the latest target is 3 per cent.) But, according to Salomon, the connection between research spending and economic growth is very loose: many other factors can matter more.

What the government should have been doing, according to the report, is actually to change the things that matter. But the author despairs whether in France anything can change. There have been 40 "re-

forms" of the French education system since 1945, Salomon counts, but none of them has finally changed anything. On the one hand, a true mass technical education remains out of reach despite frequent pious promises (of which the latest is Chevènement's, as education minister); and on the other, the top *grandes écoles*, the "engineering" schools that produce the elite of the French administration, in practice yield up graduates who "know nothing", neither science nor literature.

Also, Salomon suggests France must abandon its attachment to "great technological programmes" of state. These can only work when the state is, or controls, the purchaser; and can only fail when the purchaser is a multifarious public and the technologies various and rapidly changing (such as microelectronics). Here, the centralized French bureaucracy not only fails to be sensitive to the market but could not respond fast enough even if it were. The government should emphasize indirect action, where it has power and can change the climate, says Salomon.

• It is "indispensable" that there should be an independent, non-managerial, advisory unit to assess science and tech-

nology policy and ministerial action be established "as close as possible to the prime minister".

• The relevant ministries, with their competing and fragmented departments, should be streamlined, better directed to the marketplace.

• The "customer-contractor" principle, under which government departments should behave as customers for applied research by contract from research institutions, should be strictly applied to all big technology programmes.

• An external and public evaluation of the big technology programmes should be made "routine practice", as has become the case for the universities.

• The big programmes should take a lesser and lesser share of the cake, turning money towards "more supple and diversified" projects.

• Research and development aid to big industry must be analysed to determine if this is mere lame-duck support. Some 100 out of 1,500 French companies doing research receive 90 per cent of the government budget for industrial research and development, according to Salomon. There is danger of money going only to the strongest lobby, and more support is needed for innovative small companies.

• It is necessary to "rethink the French education system".

Cancer research

Ludwig branch lab to close

THE Ludwig Institute for Cancer Research is to close its London branch laboratories by the end of 1987. The unit, in collaboration with the Royal Marsden Hospital and the Institute of Cancer Research, is one of the major laboratories in the United Kingdom concerned with breast cancer. The Ludwig Institute has plans to open three more branches in London in the next two years and is negotiating with St Mary's Hospital, the Courtauld Institute and the Cardiothoracic Institute for sites. The staff at the present London laboratories in Sutton do not know whether they will be offered jobs at the new branches or even whether the organization intends to continue with breast cancer research. The reasons for the closure are obscure — clearly, lack of money cannot be one of them.

The Ludwig Institutes were set up in 1974 by Daniel Ludwig, one of the richest men in the world. There are at present nine branches, in the United Kingdom (2), Australia (2), Brazil, Belgium, Canada and Switzerland (2), and the organization plans to expand the number to 14. None of the branches are autonomous, but are administered by the Institute in Zurich. The present London laboratory was the first Ludwig branch to be established; its first director was Professor Munro Neville. Last year, Neville left to become a research administrator at the

organization's Zurich headquarters.

Staff at Sutton say that the post of director was not advertised after Neville left. The unit was without a director until the closure was announced, when Dr Tony Vickers, an ex-administrator from the British Medical Research Council, was appointed to oversee the rundown. Staff say that at the time of Neville's departure, the Ludwig executive assured them that the unit's future was not in doubt; eleven months later they received notice of closure. Although the technical staff have long-term contracts and are likely to be transferred, the scientific staff do not. And there is no indication that any of the new units will research breast cancer.

Scientific decisions by the Ludwig Institute are taken with the advice of a board of scientists from the United States and the United Kingdom. In the case of Sutton, staff are unconvinced that the normal procedure was followed and suspect that the decision was made at an executive level in Zurich. An explanation for the decision was promised for the staff by the end of November, but failed to materialize. Neville, speaking from Zurich this week, says that he "chose to leave" Sutton and that he knows nothing about the reasons for the decision to close it. And nobody else at the Zurich headquarters was prepared to explain the reasons for Sutton's demise.

Embryo research

West German rules proposed

Bonn

THE long-awaited report of the West German interministerial commission on *in vitro* fertilization and related matters, set up in 1984 by the minister of research and technology, Heinz Riesenhuber, and the minister of justice, Hans A. Engelhard (FDU), was published last week (25 November). Part of the delicacy of the problem in West Germany arises because *in vitro* fertilization, even when carried out with the gametes of married couples, may be incompatible with the Basic Constitutional Law except when intended to lead to the birth of a child. The commission's proposals are to guide the drafting

of new legislation in the next few months.

The commission, chaired by the former president of the Constitutional Court, Ernst Benda, voted 17 to two for the majority opinion, which says that the use of donor sperm for *in vitro* fertilization may be permissible in special circumstances; the commission recommends that children conceived in this way should have a right to be told, at the age of 16, of the identity of the sperm donor.

In general, the report says, the technique should be used only for married couples who would otherwise be unable to conceive a child. The commission would strictly prohibit the use of *in vitro* fertilization for unmarried women, and the "rent a womb" practice in which fertile women bear a child for others for payment.

The most contentious of the recommendations are those concerned with the use of embryos in scientific experiments. In general terms, the commission would forbid embryogenesis for the purposes of scientific observation, but would allow state authorities the right to grant exceptions for investigations likely to benefit "the progress of medical science". The commission's findings have been criticized for not drawing a clear line. However the freezing of human embryos would be forbidden except in exceptional circumstances.

On the cloning of human embryos, the commission unanimously recommends a total ban, suggesting that such procedures should be made criminal offences. On gene therapy, the commission argues that attempts to alter the genetic constitution of somatic cells are in principle the same as organ transplants, and should therefore be allowed, but that gene transfer within the germ line should be prohibited.

One of the most controversial issues triggered by the appearance of the commission's report is that which would allow the analysis of the individual genome as when, for example, employers may seek to determine whether applicants for jobs are constitutionally unfit to do them. Although such checks are at present impracticable, the commission has been criticized by the trades unions and SPD for approving what may one day be possible.

One of the dissenting voices on the commission, that of Walter Doerfler, professor of genetics at the University of Cologne, argues that the commission's "basic attitude" towards new developments in human embryology is "very negative" and that emotions are a poor foundation for "hurried" legislation.

The other dissenting opinion is that of Professor Peter Petersen from Hannover, a psychologist. He is opposed to *in vitro* fertilization on the grounds that the physicians involved "do not really know what they are doing".

Danube dams

Austria takes responsibility

AUSTRIA is to take over responsibility for the construction of the controversial hydroelectric plant at Nagymaros, in Hungary, the Austrian finance minister, Dr Franz Vranitzky, announced last week. The cost, estimated at 8,000 million Austrian schillings (US\$450 million), will be borne by a consortium of Austrian commercial banks, and will be repaid, over 20 years, by electricity from the new power station. The deal, however, has been criticized by Austrian environmentalists, who feel that the contract unloads environmental problems on to Hungary.

The Nagymaros dam is the lowest stage in a joint Czechoslovak-Austrian peak-hour generating scheme. A storage reservoir at Dunakiliti, on the Danube below Bratislava, will, at peak hours, feed a generating station at Gabčíkovo, through a diversion channel that will take the main flow of the river away from the international border through Slovak territory. The Nagymaros dam, on the scenic Danube bend between Esztergom and Budapest, in addition to producing electricity for Hungary (and now, for Austria), will serve as a catchment for surges from Gabčíkovo.

Many Hungarian environmentalists have opposed the scheme, on the grounds that it will destroy the Danube wetlands which are the habitat of rare flora and fauna, ruin the amenity value of the bend (Budapest's chief resort area) and, by lowering the water-table, cause a pollution threat to the water supply of Budapest. The Hungarian government, the environmentalists urged, should either get Prague to agree to drop the scheme, or else withdraw unilaterally. Both courses, however, proved impractical politically, and in mid-August the Hungarian government reiterated its commitment to the scheme, though now with a postponed timetable and assurances of careful ecological monitoring.

Ironically, virtually the same environmental objections that the Hungarians had to the Dunakiliti-Gabčíkovo-Nagymaros installations were raised by the Czechoslovak government against Austrian plans to build a similar storage reservoir and power station at Hainburg.

In November 1984, the Czechoslovak foreign ministry announced that if the Hainburg dam were built, Czechoslovakia would demand massive compensation for ecological damage. A month later, after a long battle with the Konrad Lorenz Volksbegehren, Austria's main environmental organization, the Austrian government halted land-clearing operations at Hainburg, and, it now appears, began negotiating for a financial stake in Nagymaros.

Vera Rich

UK money for AIDS

MR Norman Fowler, Secretary of State for Social Services, this week announced that the British government would spend an extra £6.3 million on a package to combat the spread of acquired immune deficiency syndrome (AIDS). The money will be divided into five parts: £2.5 million for a national information campaign; £2.5 million for the Thames regional health authorities (75 per cent of the reported cases of AIDS in the United Kingdom are in London); £270,000 for six haemophilic counselling centres; £100,000 for training health professionals; and £750,000 for the Public Health Laboratory Service for testing blood samples for the AIDS virus.

The latest figures for the United Kingdom show that, of the 231 men and 10 women who have reported that they have the disease, 134 have died. A prediction of 1,837 new cases by 1988 was made at a meeting in London last week; the figure is higher than previous estimates because intravenous drug abusers are thought to be much more at risk than previously realized. The worry is that this group may be less amenable to public information campaigns than other "at risk" groups.

In a study published in the *Lancet* last month, it was reported that 38 per cent of serum samples from 106 Edinburgh drug abusers were positive for antibodies to the AIDS virus, with the proportions of men and women who registered seropositive about the same. Another report in the same issue analyses Centers of Disease Control data and shows that the relative risk of AIDS is four times greater for intravenous drug abusers than for homosexuals in the United States.

● The College of Health in London this week launched an addition to its Healthline service, which provides tapes of information on a range of medical subjects. Twelve new tapes give information on various aspects of AIDS; they can be heard by calling a London telephone number (1-980-4848) between 6 and 10 pm. Maxine Clarke

Polish universities

Government launches purge

At least 40 leading Polish university officials will lose their jobs as a result of the 1985 amendments to the Higher Education Act. The amendments increased the control of the Ministry of Science and Higher Education over the universities, and in particular, curtailed the rights of the universities freely to elect their own rectors, pro-rectors and deans. Despite assurances from government spokesmen last July that the changes then before the Sejm (Parliament) did not signal a purge in the universities, few academics were convinced. Their pessimism, it appears, was justified.

Under the amendments, rectors, pro-rectors and deans now in office will receive written confirmation of continued tenure from the ministry not later than the

end of January 1986, or else will be replaced. On 3 November, the underground newsletter of the pro-Solidarity Social Committee for Learning warned that the ministry planned to change the whole team of rector and four pro-rectors at Poznan's Adam Mickiewicz University.

This was surprising. Although the minister refused to confirm in office the rector elected in spring 1984, Professor Jerzy Fedorowicz, the current rector, Professor Franciszek Kaczmarek, a physicist, seemed an acceptable compromise.

Since then, however, there have been several pro-Solidarity incidents at the university. Moreover, the current Minister of Science and Higher Education, Dr Benon Miskiewicz, was the rector until his promotion to the post of minister shortly after the declaration of martial law. It seemed possible, therefore, that Minister Miskiewicz had singled out his own university as an example.

According to the Social Committee for Learning, the new rector was to be Professor Jacek Fisiak, a personal friend of the minister and a party hard-liner. Fisiak is a man of many parts. As head of the English department, he was responsible for the dismissal from the university, in 1978, of Dr Stanislaw Baranczak, the gifted poet and translator of English literature into Polish. He holds a British civil decoration, the Order of the British Empire, for his services to English studies in Poland.

Now, it appears that, according to Mr Andrzej Stolarski, chief spokesman for

the Ministry of Science and Higher Education, the new law specifically provides for a review of academic personnel throughout Poland, a statement somewhat at odds with the previous assurances. The Main Council for Higher Education, the supreme elected representative body of universities and higher colleges which, during the last academic year coordinated the campaign of the universities against the proposed revision of the law, met in closed session last Friday, but made no immediate statement. The Main Council, however, is known to be out of favour with the minister, who attacked it in parliament as being unrepresentative of the higher education community. It seems unlikely, therefore, that the Main Council will allow the dismissals to pass unquestioned.

Since the dismissals refer, so far, only to administrative posts, the rectors, pro-rectors and deans affected by the "review" will still, for the present, be able to carry on teaching — although there are strong rumours that the minister's next plan is for a "review" of teaching staff.

One rector who is to pay the price for putting his duty to his students before the demands of the authorities is Professor Wladyslaw Findeisen of Warsaw Polytechnic, who last year refused to identify and discipline those of his students who had carried the university banner at the funeral of the murdered Solidarity priest, Father Jerzy Popieluszko. The news of his dismissal last week evoked a massive and emotional demonstration by the polytechnic students, who gathered in the Great Hall of the Polytechnic. When the rector appeared, the students showered him with flowers.

Vera Rich

One US-Soviet pact

Washington

WHILE President Ronald Reagan and Mikhail Gorbachev were getting acquainted in Geneva the other week, another relatively unknown US-Soviet meeting was taking place in Moscow. Lee Thomas, administrator of the US Environmental Protection Agency (EPA), and Yuriy Izrael, chairman of the USSR State Committee for Hydrometeorology and Control of the Natural Environment, signed a memorandum presenting plans for cooperative work on 38 scientific and technical projects in the general field of monitoring the environment.

The meeting was the first high-level meeting on environmental cooperation between the two countries for six years. It took place under the auspices of a bilateral agreement originally signed in 1972 and since extended. Though the agreement has never been abandoned, deepening strains between the two countries had led to a steep decline in the number of scientists exchanged, from over 300 in 1977 to only 67 in 1984.

US officials say the United States has benefited in the past from the agreement, especially in earthquake prediction and environmental transport modelling. There have also been some difficulties: visas are often not available until the last minute, and last year one US official who had visited the Soviet Union several times under the agreement was suddenly denied a visa and slandered in *Izvestiya*.

At the recent Moscow meeting, eight areas of cooperation that had not been fruitful were abandoned, and four more were initiated. Nevertheless, the total number of scientific exchanges under the agreement is now expected to increase once more, according to Dr Gary Waxmonsky, EPA's executive secretary of US-Soviet programmes.

Tim Beardsley

Max Planck Gesellschaft

More cheer for Eureka than SDI

Bonn

THE Max Planck Society (MPG) seems eager that its 60 institutes and 10,000 employees should contribute to the European Eureka programme of technological research, but wary of the possibility that they might be caught up in the US Strategic Defense Initiative (SDI). So much emerged last week (27 November) when Professor Heinz A. Staab, the president of the society, introduced its annual report.

Professor Staab announced that the Max Planck Society is playing a leading part in one of the first Eureka projects, an inter-Europe collaboration in atmospheric chemistry. He said that the objective of the Eureka programme, at least as seen by MPG, is to complement the "existing one-way street to the United States" by more interconnections within Europe.

On SDI, Staab said that MPG has not so far been asked by the West German government to consider playing a part, so that MPG had not given formal consideration to the project. But he added that he could

not imagine that secret research could be carried out at any of the society's 60 institutes. He went on to say that plans for the development of basic research should not be "slipped over the scientific community" by politicians, whose influence should be used to strengthen existing collaborations.

MPG had funds of more than DM1,000 million to spend this year, and its budget of 1986 represents an increase of 3.8 per cent. But after allowing for the start-up costs of two new institutes, one for polymer research at Mainz and another for sociological research at Cologne, the increase for next year works out at only 2.8 per cent. Staab complained last week that the finance ministers of the *Länder* governments, which are responsible for half of MPG's budget, had originally worked for a mere 3 per cent increase of the total budget. Even now, Staab said, the increase would not be sufficient to cover the cost of inflation, reckoned to amount to between 5 and 6 per cent a year in the cost of research.

Planetary exploration

US Mars lobby gathers strength

Washington

THE "Mars underground", a network of enthusiasts dedicated to persuading the US government to support a manned mission to Mars, has again been raising its voice in public, pressing its case for a permanent base on Mars to the National Commission on Space. The signs are that it is being taken seriously.

The movement is made up both of university-based researchers and many in the National Aeronautics and Space Administration (NASA). As long ago as the early 1960s, NASA commissioned studies to investigate the feasibility of Mars missions, but enthusiasm waned as manned Moon landings became routine and the Apollo programme was brought to a premature close. But now the Mars underground seems to have found new strength.

Mr Leonard David, director of research of the National Commission on Space, is one of the biggest supporters of Mars ventures. He is to present a report on the future of the civilian space programme to the President and Congress by March 1986. The commission, appointed by President Reagan earlier this year, was explicitly told to take a bold long-term view, and it seems to be doing just that. It will look at options for the period to 2035 or even beyond, and will be taking a hard look at the Mars base plan as well as at proposals for a manned lunar base.

David points out that Mars has for many years been a vague long-term goal for NASA. With the shuttle now working at

least tolerably well and a space station apparently not too far off, the question that will arise is what they should be used for — whence the "case for Mars" group, which presented a 150-page summary of its plans to the commission last week at Stanford, California.

The group expects to use the first permanent manned bases on Mars established between 2010 and 2020; before then, though, bases may have been established on Mars's moons, Phobos and Deimos, which may contain enough water to use as a source of hydrogen and oxygen for fuel. The effort would be international and, after initial unmanned exploratory missions, the first crew of about 15 people would arrive for a ground spell of duty of up to two years.

The group lays much stress on using martian materials wherever possible, and notes that the martian atmosphere contains a high proportion of carbon dioxide, which could supply many essential needs for a permanent base.

The National Commission now has to weigh these ambitious plans against the rather less exciting lunar base plan. According to David, a lunar base might be a spin-off from a Mars base plan but is not generally thought to be an essential precursor. But there is one extra factor arguing for a Mars effort which could prove the most important of all: the Soviet Union has already spoken of plans for a manned Mars mission as early as the middle of next decade.

Tim Beardsley

Remote sensing

France puts trust in SPOT

SPOT 1, the first of two French observation satellites, is to be launched by Ariane on 11 January, only a few weeks late despite the failure of the last Ariane launch on 13 September. Arianespace, the commercializer of Ariane, will be crossing its fingers that adjustment to the design of a valve in the third stage will seal the leak of liquid hydrogen that caused the failure. So will the French space agency CNES, which has designed SPOT and which hopes it will steal the thunder from the US Landsat series of satellites.

CNES claims that twin high-resolution imaging instruments on SPOT 1, operating in the visible and near infrared, will be capable of identifying details down to about 10 metres, compared with the 30 metres of the last Landsat (Landsat 4) launched in July 1982).

CNES emphasizes, however, that the great innovation of SPOT is not so much its resolution as an ability to look away from the vertical. By this means, the satellite can in two passes some 90 minutes apart image the same Earth region from different angles, thus generating three-dimensional images. Simulations of such SPOT images have been made from aircraft, and they are certainly spectacular to view. These images should contain quite new cartographic information on vast regions of the more inaccessible parts of the Earth, and pose new challenges for information processing.

CNES has established a number of ground stations for receiving SPOT data, at which the data will be processed into directly usable images. In France, the principal station will be at Toulouse, where SPOT was designed and where all SPOT imagery is to be kept. A company called Spot Image has been established to sell and distribute images.

SPOT 1 will be accompanied into space, if all goes well, by the first Swedish scientific satellite, VIKING.

Subsequent Ariane launches are planned for February (two communications satellites, one for the US GTE Spacenet Corporation and one for the Brazilian government) and March (Intelsat V). Five additional launches are planned for 1986. Arianespace has also announced that despite its September setback, three institutions have since purchased future Ariane launches: one to orbit the first Luxembourg television satellite, which will broadcast to most of Europe, and one for a communications satellite for INMAR-SAT (the International Maritime Satellite Organisation).

These orders bring the total number of launch contracts of Arianespace to 37, of which 25 remain to be launched, the company says.

GE aims at super-array contract

Schenectady, New York

GIANT General Electric (GE) is in the final stages of negotiating a contract with the US Department of Defense to complete the development and to begin the construction of what could be the world's most powerful computer.

The multimillion dollar project, a collaboration between GE's research and development centre here and the Artificial Intelligence Laboratory at the Massachusetts Institute of Technology (MIT), is for the construction of a machine with no fewer than 256,000 processors. Those responsible for the project wryly note that the new machine, called the Cross Omega Connection Machine, will have 100 times as much computing power as all the computers now installed at the centre.

The practical objective of the development is to construct a computer capable of processing in parallel the information in each picture element (pixel) of a standard 500 by 500 cell image. Suitably miniaturized, such a system could be carried by spacecraft or tanks and could make intelli-

gent decisions about the best response to incoming signals in video form.

The speed of the parallel array will be phenomenal — one million million operations a second. GE says that the architecture of the machine will be entirely novel, and that it will represent a milestone in the development of computing machinery. But the construction of the processors is also novel. By means of Very Large Integrated Circuit techniques, 64 processors will be incorporated on each of 4,000 semiconductor chips. By the use of optical lithography, GE claims that it now has in production at its plant at Research Triangle Park, North Carolina, integrated circuits with linewidths of only 1.2 micrometres, and that the research laboratory has made microcircuits with linewidths of 0.4 micrometres.

But Dr Phil Lewis, head of GE's computer science branch at Schenectady says: "We have to make a whole new computer science for this machine. And nobody knows how to do it."

Japanese nuclear power

Straining at the US leash

Tokyo

JAPAN'S nuclear power industry, held back by US restrictions of fuel enrichment and reprocessing for more than a decade, has taken a great bound towards partial self-sufficiency in the production of its fuel, but probably in the wrong direction. Barely had the ink dried on an agreement with local officials to build a uranium enrichment plant based on centrifuge separation than the US Department of Energy sent shock waves through the Japanese industry by announcing that laser enrichment may be more economical. If this proves true, Japan's first commercial uranium enrichment plant due to open in 1991 will be outmoded and uneconomical.

Early this year, the governor of Aomori prefecture signed an agreement with Japan's Federation of Electric Power Companies for construction of a nuclear-fuel cycle complex in the prefecture on the northern tip of mainland Japan. It allows for plants for fuel enrichment and reprocessing as well as low-level waste storage. Although shaken by the US decision in June to switch to lasers, the Japanese government decided in October to press ahead with the enrichment plant next fiscal year, and a delegation was despatched to Washington in mid-November to seek revision of the 17-year-old Japan-US Atomic Power Agreement.

Behind these developments lies a 10-year struggle by Japan to break free of the US constraints which require "prior consent" before US fuel can be reprocessed. In 1972, Japan's Atomic Energy Commission recommended that commercial reprocessing plants should be developed after experience with a prototype plant, built by 1974 at Tokai-mura, north of Tokyo, by the Power Reactor and Nuclear Fuel Development Corporation (PNC), a semi-governmental research and development organization affiliated with the Science and Technology Agency.

With the tightening of US policy which the Indian nuclear explosion in May 1974, the start-up of operations at the Tokai plant was delayed by US restrictions until 1977, after Japan had signed the Treaty on Non-Proliferation of Nuclear Weapons. The delays by the Ford and Carter administrations raised bitter feelings, striking as they did at the heart of Japan's desires for energy self-sufficiency. PNC opened a centrifuge enrichment pilot plant at its Ningyo Toge works in 1979, and the steady trickle of fuel from this plant and the Tokai reprocessing plant has been used in PNC's prototype heavy-water reactor FUGEN and will be used in the prototype fast breeder reactor MONJU.

PNC has been less successful with its plans for radioactive waste storage. Last month it caused an uproar at Horonobe, a small town in the northern island of Hol-

laid, where it had planned a site for high-level storage with the approval of the town but in the face of opposition from the governor or Hokkaido, other local government leaders and residents. The Council of All-Hokkaido Labor Unions had mobilized a daily vigil by 300 members, reduced to 40 at weekends. PNC officials sneaked onto the site two weeks ago to choose sites for boreholes and for the location of a seismograph as well as to collect rock samples. A spokesman for the corporation said the inspection was carried out without notice to "avoid possible confusion among local residents".

Waste storage facilities will also be an integral part of the new complex to be built in Aomori. Around 66 million litres of low-level radioactive waste are at present stored at nuclear plants around the country. Earlier tentative plans to dump the waste in the Pacific from other Pacific countries, so that the Aomori complex will have storage space for up to one million 200-litre drums of waste in the first

stage and three million in the second have met with strong opposition. Proximity of the storage site on the Shimokita peninsula to the Misawa air base has raised fears of air-to-ground weapons going astray or crashing jets, but others favour the development as a stimulant to local economy.

Unlike the reprocessing and enrichment plants run by PNC, which are largely experimental in nature, the complex at Aomori will be a fully commercial enterprise backed by MITI and run by Japan Nuclear Fuel Industries Inc., a consortium established by the electric utilities and machinery companies in March this year. The plan is for Japan to produce domestically about 30 per cent of its enriched uranium needs by 2000. Japan would then be free to reprocess such "home-grown" fuel without prior consent from the US.

This panacea for Japan's dependence on energy imports may never materialize, however, if the laser-beam method of enrichment is successfully developed by the United States. Realizing this, the Japanese government announced in October plans to establish a joint government-private industry organization to develop the method.

Soviet *refusniks*

French scholarship in absentia

THE Paris-based Comité des Professions Médicales en faveur des Juifs d'URSS has established a bursary for *refusnik* scientists, taking the form of an invitation to study for a year in France. The award is to be called the Victor Hugo bursary to mark the appointment in 1882 of Victor Hugo as president of an emergency committee to help the Jews of the then Russian empire.

The first "recipient" will be Karen Khatchuryan, a 24-year-old ex-student of physics who was expelled from Moscow University in 1981 for "behaviour inconsistent with the name of a Soviet student" — in other words, for having filed an application to emigrate to Israel.

Whether the young man will be able to benefit from the award seems doubtful. If he was unable to obtain permission to emigrate to Israel, it seems unlikely that the Soviet authorities will let him go to France.

The bursary was announced during a meeting at the Paris Palais de Congrès devoted, in the first place, to medical problems relating to Soviet Jews. Some telling anecdotal evidence was presented on the decline in the proportion of Jewish school-leavers entering medical schools, particularly the distinguished establishments of Leningrad, Moscow, Kiev, Khar'kov and Vil'nyus.

Another panel dealt with the personal problems of the children of *refusniks*, forced to lead a double life between the Soviet culture they experience in school and the Jewish culture of their parents. Dr Albert Mallet, a psychiatrist who has vi-

sited the Soviet Union on several occasions, says that out of some 80 children examined, about half have developed serious personality disorders directly associated with their enforced lifestyle.

The third main panel at the meeting dealt with the political misuse of psychiatry. The case of Dr Zakhar Zunshain, a Jewish physicist from Latvia, suggests a change of Soviet practice. Undated copies of correspondence between Mrs Zunshain and the Deputy Minister of Health of the Latvian SSR, made public at the meeting, show that Dr Zunshain, a professor of physics who was sent to labour camp in March 1984 for having taken part in a demonstration outside the Bolshoi theatre in Moscow, had on some prior occasion been visited by a psychiatrist, at the request of the local police.

When Mrs Zunshain tried to obtain an explanation of this occurrence, the Deputy Minister, K. Berman, replied that it "should be considered quite normal". When denied a visa to emigrate, Dr Zunshain had refused to take "no" for an answer, and had continued to write "non-pertinent declarations which contained insults to the officials responsible", causing "serious doubts as to his mental health". The health law of the Latvian SSR, wrote Berman, provides for "prophylactic examination of citizens whose conduct and actions are characterized by a lack of critical spirit and opportunity", a ruling, which, if it were generally applied, could put the entire *refusnik* community at risk.

Soviet seismology

Tajikistan earthquake reveals flaw

LAST month's earthquake in the Soviet republic of Tajikistan caused unnecessary damage, according to the local correspondent of *Izvestiya*, V. Surkov. The planning authorities of the Tajik SSR, he says, have for a long time "resisted" the classification of Leninabad *oblast'*, in the north of the republic, as liable to suffer earthquakes of force 8 on the Soviet 12-point scale. Not only had buildings been built to specifications suitable only for less seismic zones, he claims, but Leninabad city itself does not have a single seismic station.

Tajikistan is the most seismically active region of all the Soviet Union's 2 million km² of earthquake-prone terrain. The industrialization and development of the region has therefore called for considerable circumspection on the part of the geologists, and seismic risk maps for centres of population have been in existence for a number of years.

The latest forecast for Leninabad *oblast'*, which dates from 1982, increased the predicted maximum shocks from force 7 to force 8. The republic authorities, however, Surkov said, were reluctant to act on the new figures, and neither strengthened existing buildings nor modified the specifications for new ones. As a result, in the earthquake of 14 October, the towns of Kairakkum and Gafurov suffered heavy material damage.

Surkov's dispatch, from Leninabad *oblast'*, contradicts the impression given by earlier reports from the TASS correspondent, Aleksandr Nemirovskii, who filed from the Tajik capital of Dushanbe. According to Nemirovskii, "residential quake-proof houses built in recent years withstood the force-8 shock". This may be technically true — Surkov implies that some 10 per cent of housing was at least reparable — and Nemirovskii did go on to say that some people who had lived in old houses had had to be given shelter in tents, but the extent of the devastation, and the allegations of official negligence, come only from Surkov.

It is possible that even if the buildings had all been up to recommended standards, they might not have survived, since the shock in fact exceeded force 8. This means, Surkov notes, that future buildings in the area ought to be constructed to resist at least force 9. But some Soviet civil engineers seem doubtful about high-rise,

construction in seismic areas, and after the Gazli earthquake of March 1984 it was decided to replace devastated apartment blocks with one-storey dwellings.

More significant, perhaps, is Surkov's claim that Leninabad *oblast'*, which accounts for one third of the population of Tajikistan, has insufficient seismic monitoring stations. Earthquake prediction is a major concern of Soviet geology. Recommended methods range from sampling the helium content of geothermal waters to observing the behaviour of local fauna.

The most reliable early-warning sys-

tem, however, if populations are to be evacuated and emergency services alerted, is the continuous monitoring of microtremors, which are then processed by computer to establish forecasts of the expected epicentre and strength of imminent earthquakes.

In Leninabad *oblast'*, there were not only too few monitoring stations but the communications links to the Central Asian Seismic Forecasting Centre in Dushanbe did not operate. The earthquake itself, moreover, damaged telephone lines to the devastated areas, so that emergency rescue services, while fully aware that their help was urgently needed, had no idea where to send it.

Vera Rich

Japan in chaos

Radical attacks halt railways

Tokyo

As in other advanced nations, the functioning of Japan's giant cities is very much dependent on fast urban transport systems and the sophisticated electronic communications that control them. Just how vital these communications systems are was shown when left-wing radicals, protesting at plans to privatize the national railway network, last week cut trackside cables in Tokyo and Osaka. Eleven million commuters were stranded and for half a day many businesses ceased to function.

Almost exactly a year ago, a small fire knocked out computer links and brought Japan's banking system to a halt (see *Nature* 312, 393; 1984). At that time, there was an outcry over the vulnerability of the emerging back-up systems. But it seems that ultra-left groups learned more from that incident than did the government.

Early on Friday morning, radical groups, armed with garden shears and knowledge of where to find the cables for the national railways' central traffic control and automatic train stop systems, struck at 23 locations in the Tokyo area. The first the railway authorities knew was when screens at the central computer headquarters went blank; when they tried to contact key stations through their own telephone network, that too was found to be dead. Similar events took place in Osaka. That morning, the two cities' entire public rail systems were paralysed.

Repairing the cables is a difficult task: a minimum of four hours is required when a single break is made in the more sophisticated communication links. When there are several cuts in the same cable, the difficulties are multiplied many times over. During the day, huge traffic jams developed and enormous queues formed at the stations of the private railway line still running. One queue in Tokyo was said to consist of 35,000 people. Businesses opened late and a fifth of Tokyo's schools closed for the day.

In a related incident, other radicals,

dressed in business suits and ties but wearing helmets, attacked a medium-sized station in the centre of downtown Tokyo with Molotov cocktails. They then flung away their helmets and disappeared among the crowds of commuters. The station burned throughout the day.

No statement has been issued by the attackers, but it is assumed that they were members of the People's Revolutionary Army of the ultra-left Chukaku-ha (Middle Core Faction). Their attacks were timed to coincide with a strike by a break-away chapter of the National Railmen's Union based in Chiba, a little to the east of Tokyo, protesting against plans to privatize the National Railways.

The Chukaku-ha is a strong and well-organized revolutionary group with probably around 3,000 members, many of them recruited at universities. Membership of its secret revolutionary army probably numbers several hundreds.

Previously, the group has been most conspicuous in its bitter fight against the construction of Tokyo's new international airport at Narita. Although the airport was opened seven years ago, the radicals are still fighting for it to be closed and for land expropriated from small farmers to be returned. The airport is constantly guarded by some thousand police, but this has not prevented frequent disruptions in service.

That radicals now seem willing to use similar tactics against the railways is bad news for the Japanese government. Railway authorities have already admitted that there is no way they can guard hundreds of kilometres of communication cables against attack, nor can they install a complete back-up system without ruinous expenditure. Selling off the railways is going to be a considerably tougher task with radical opposition which could continue indefinitely. And police fear that the Chukaku-ha may be planning something big for the Tokyo summit of world leaders next May.

Alun Anderson

British civil plutonium

SIR—Barnham, Hart, Nelson and Stevens (*Nature* 317, 213; 1985) conclude that at least 2.3 ± 0.8 tonnes of plutonium produced by the magnox nuclear stations of the UK generating boards cannot be accounted for, and may have been diverted to weapons use. An earlier version of this paper was submitted by the Campaign for Nuclear Disarmament (CND) to the Sizewell B Public Inquiry where it was debated at length. The Central Electricity Generating Board (CEGB) demonstrated that the analysis was in substantial error and no credence could be placed on its conclusions or, of course, the implications that the authors were striving to secure therefrom. While the revised paper takes account of some of the comments made by CEGB, the main criticisms still apply. These are as follows.

(1) The paper derives the estimate of 2.3 tonnes by attempting to calculate the total plutonium from the CEGB and South of Scotland Electricity Board (SSEB) stations since 1963, and compares this estimate of 47 tonnes with the amount the government has accounted for in parliamentary statements, augmented by the amounts the authors estimate to be in civil use in the United States, and to have been lost in reprocessing. Since the approach depends on estimating the difference between two large numbers, the conclusion is critically dependent on the accuracy of the calculations — clearly the calculation of plutonium production needs to be accurate to better than 5 per cent for the claimed discrepancy to be of any significance. It follows that a very careful calculation is necessary to obtain results of the accuracy needed, but although the paper claims an accuracy of ± 2 per cent, this is not substantiated. In particular, an accurate estimate is needed of the plutonium production as a function of irradiation; this requires calculations for each station using detailed data on station design and operation, and a theoretical model more complex than the simplified method adopted in the paper, which uses approximate data culled from a variety of sources. Since the three different methods of calculation described in the paper all use the *same* estimate of plutonium production as a function of fuel irradiation (the function $G(B)$), the three methods are not independent. The degree of agreement between their results provides no evidence on the accuracy with which this plutonium production function has been calculated.

(2) The authors attempt to validate their overall method of calculation by comparing estimates of plutonium production over a 6-year period with data provided by CEGB for amounts of plutonium in irradiated fuel despatched for reprocessing from each of our eight magnox stations. Table 4 of the paper concludes that this shows that their model underestimates

plutonium production by 3.7 per cent, implying that their estimate of 2.3 ± 0.8 tonnes for plutonium unaccounted for is an underestimate by $0.037 \times 47 = 1.7$ tonnes. However, as CEGB explained at the Sizewell Inquiry, this comparison is not valid because it does not allow for changes in the level of irradiated fuel stocks at the stations over the six-year period. The comparison is also selective since the paper reports the comparison for seven of the stations but excludes the data provided for the other station at Wylfa. If Wylfa is included, the results are substantially changed — the overall ratio of plutonium dispatches to calculated production changes from 1.037 to 0.948. If the authors had not excluded the data for Wylfa, they would presumably have concluded that the comparison shows their method overestimates plutonium production by 5.2 per cent and that the claimed discrepancy of 2.3 ± 0.8 tonnes is *overestimated* by 2.4 tonnes.

The board is not able to publish a definitive analysis of plutonium production for reasons that were explained at the Sizewell Inquiry. These relate to the period before 1971 when some of the plutonium produced, although itself remaining in civil use, was bartered with the United States for a quantity of highly enriched uranium which was used for defence purposes. It has been the policy of governments over the years not to disclose this figure, and we are also precluded from providing detailed information which would help others to derive it.

To sum up, the accuracy of the authors' calculations is not sufficient to support the allegation that plutonium produced in civil reactors in the United Kingdom may have been diverted to weapons use.

Repeated statements in Parliament by ministers have confirmed that no plutonium produced in CEGB reactors has been used for military purposes in the United Kingdom or exported for use in weapons. The government has also stated that it has no plans to use plutonium produced in the board's reactors for nuclear weapons and this is also the policy of the US government.

Free will

SIR—Nothing is gained by the invocation by D. H. Evans (*Nature* 307, 762; 1985) of the second law of hydrodynamics.

It may be true that free will implies the ability to think divergently; but determinism does not imply convergent thought: it implies only determinism. Given that the

thought processes of the scientist are the result only of causes in his environment, they can appear as convergent or divergent. They are convergent when the observer (who is also determined) perceives nothing new (in Evans' terms, no loss of entropy) which could not have been deduced logically from the observed facts. They are divergent when the observer perceives something new (either not deducible or apparently unrelated) which can subsequently be demonstrated by experiment. However, an observer with access to all the facts (that is, the whole internal and external environment of the scientist) might perceive the deductive logic of "divergent" thought.

Free will implies that the scientist has control over his divergent thought (which is intuitively absurd) while determinism implies only cause and effect. Convergence and divergence are then functions of the observer's environment, not the scientist's environment.

The entropy of the situation is more straightforward. Entropy is different in spatial and temporal regions of the Universe, and the variability might arise as a result of local fluctuations and aggregations. Given a spectrum of entropy, its value in one region is a statistical function (deterministically predictable but otherwise chosen (!)) and in any given region can be very high or very low. Thus in the spatial regions of living forms it can be very low: temporally it may continue to fall before it rises again.

Consciousness may indeed be a manifestation of biochemical processes, and the brain may function far from thermodynamic equilibrium: but that does not prevent it being determined in the same way that a whirlpool is determined.

Academic tenure

SIR—The question whether those who work as professors or researchers at academic institutions should enjoy security of tenure has been much discussed (see, for example, *Nature* 317, 464; 1985) but surely, in democracies, if job security is to be eroded for some, the same rules should apply to others. Yet in the armed services, those who graduate from military academies and similar institutions have tenure for the rest of their lives. They may be asked to retire early but are compensated with a pension, and at no point are they required to justify their promotion, largely automatic, by enumerating the battles they have won or the missiles they have fired accurately, the military equivalents of papers published or graduate students trained. Can this be fair?

Competition for big time opens

The launching of the Hubble Space Telescope next year will provide up to 3,000 hours of the best-ever telescope time. Here is how to bid for some of it.

THOSE hoping for a share of the time that will be available to users of the Hubble Space Telescope will at least now know to which address to write*. Towards the end of last month, the Space Science Institute on the Johns Hopkins campus at Baltimore put in the mail some thousands of copies of its formal *Call for proposals*, a document that explains the procedure applicants for telescope time must follow, together with more than a kilogram of supporting data, not to mention application blanks (twelve copies of which must be returned).

The documents give as full an account as there could be of how the potentially contentious issue of time allocation will be dealt with by the Space Science Institute. They are also, in passing, a vivid reminder of the potential power of the Hubble telescope, a 2.4-metre reflector equipped with instruments sensitive to radiation from the infrared (11,000 ångströms) to the ultraviolet (1,150 ångströms).

That the instrument will do more for observational astronomy than the building of the Hale telescope on Palomar Mountain in the 1930s seems generally accepted; it could yet outdo Galileo's contribution to the craft of observation. So competition for telescope time will be fierce.

So why will there be only 3,000 hours, rather less than 10 hours a day, of observing time each year? The new documents make plain the uncertainties that persist, the chief of which is that no date has yet been fixed for launching the telescope by means of the US space shuttle. And in the nature of things, nobody can guarantee that the instrument will find its way into orbit (at an altitude of 500 kilometres with an inclination of 28.5 degrees).

But the documents also explain that the efficiency with which the telescope can be reoriented towards novel targets is still an unknown quantity, whereas observations will not be feasible while the axis lies too close to the direction of the Sun, or the bright limbs of the outline of the Earth.

Applicants will also have to take account of the annoying complication of the South Atlantic Anomaly, the departure from regularity of the Earth's magnetic field that allows charged particles trapped in the magnetosphere to reach down

into the orbit of the telescope; the telescope detectors will be unusable not merely during passage through the anomaly but for an unquantifiable length of time thereafter, while the phosphorescence of the detectors makes the noise unacceptably high. One consequence is that the longest period of time when the continuous viewing of a target will be possible is estimated to be between 10 and 12 hours, a little more than at a high-latitude terrestrial observatory on a clear winter night.

The opportunities, on the other hand, are immense. The focal plane of the mirror is equipped with a variety of instruments, to each of which is assigned the radiation intersecting a predetermined patch of the plane, allowing the remainder of the radiation collected by the telescope to be gathered into the synoptic images of the wide-field camera (with the comparatively small field of view 154 arc-seconds square). This instrument will be able to acquire images, always in digital form, with a visual magnitude of 28. Perhaps more striking is the expectation that the use for astrometry of one of the three fine guidance sensors with which the telescope is equipped (two are needed for pointing the telescope) will allow angular positions to be determined to within 0.0016 arc seconds. This expectation, if borne out by experience, implies that it will be possible directly to determine the distances to important milestone stars used in constructing the distance scale of the Universe.

So how are these great opportunities to be shared? In principle, according to the Space Science Institute, anybody may apply for time. All proposals will be put through the same peer-review system, and time allocated on merit.

On the teasing question of deciding between the merits of proposals yielding quick spectacular results and long-term programmes bearing fruit only after the accumulation of a mass of data, the institute plans an arbitrary but workable solution. Each proposal will be considered by a disciplinary review panel, but final recommendations will be made by a Telescope Allocation Committee with general instructions to allocate roughly equal amounts of time to proposals in the categories small, medium and large. These allocations will account for roughly 90 per cent of the time, with the remainder reserved for allocation by the director, among other things so that unexpected opportunities may be seized and so that

the telescope may be used in novel ways.

The institute has already settled on three key projects to which special attention will be given, of which the chief is the determination of the distance scale, ideally so as to determine Hubble's constant to within ten per cent. The second consists of an invitation to exploit the potential of the wide-field camera so as to carry out a deep survey of selected regions of the sky, yielding information on such miscellaneous issues as the comet cloud beyond Neptune and the supernova rate in distant galaxies. Quasar absorption lines come third.

Speed will obviously be crucial. The documents make plain that applications for time will not succeed if the objective is a project identical with one already in the programme. Thus the first convincing proposal to measure Hubble's constant is likely to hold sway for two or three years. The other side of this coin of exclusivity is the institute's policy on the publication of data. At the outset, an observer will have exclusive access to the data gathered on his behalf for twelve months after the last of them have been stored, but thereafter, the data will become part of the general archive at Baltimore.

So how should intending applicants proceed? First, read the instructions carefully. The chances of being caught out by misunderstanding the technical performance of the instruments, or by miscalculating the length of the exposure required, are high. Those who succeed in the first round of applications will find themselves quickly asked for accurate positions of the guide stars they specify for their targets. Perhaps the best hope of winning time early is to go carefully through the list of projects put forward by those guaranteed exclusive use of the first six months (people who have helped to develop the telescope), looking for opportunities to make parallel observations of objects within the field of view of the Hubble telescope during that initial period.

But can it be worth the trouble when there is always a risk that the telescope may not be launched successfully? The risk of failure is no greater than that the shuttle itself might fail. But, whatever happens, the list of proposals on their way to Baltimore in the next three months is likely to serve future historians well as a record of the ambitions of the world's astronomers at this interesting time.

Evolutionary biology

Sex ratios in wasps and aphids

from Robert M. May and Jon Seger

DARWIN seems to have framed most of the major problems in evolutionary ecology, and to have showed, at least in outline, how they might be solved. But he failed to crack the problem of the sex ratio. "In no case . . . would an inherited tendency to produce the sexes in equal numbers or to produce one sex in excess, be a direct advantage or disadvantage to certain individuals more than to others; . . . I formerly thought that when a tendency to produce the two sexes in equal numbers was advantageous to the species, it would follow from natural selection, but I now see that the whole problem is so intricate that it is safer to leave its solution for the future."¹ The future began in 1930 with R.A. Fisher; that it continues is shown by papers in *Science*² and this issue of *Nature*³.

Fisher pointed out that if we count grandchildren (rather than children), then it follows at once that there is an advan-

tage to producing the minority sex, whose members enjoy greater reproductive success, on average, than do members of the majority sex⁴. Thus males and females will be produced in equal numbers at the evolutionary equilibrium. If the cost of producing a male offspring differs from that of producing a female, then we need to state Fisher's result in its more general form, which says that at the equilibrium there is equal total investment in the two sexes. Darwin might easily have discovered this principle some 60 years before Fisher, had he thought to look ahead two generations instead of one when evaluating an individual's reproductive success.

Fisher's result assumes that there is population-wide competition for mates. In 1967, Hamilton⁵ showed that the ratio to investment may be dramatically female-biased under certain kinds of mating systems in which, owing to the physical

isolation of sibships, brothers compete to inseminate their sisters. Hamilton marshalled evidence demonstrating large female biases in a number of insects (mainly parasitoid wasps) that are likely to experience intense 'local mate competition' (LMC).

Hamilton's paper stimulated interest in many different kinds of problems concerning sex allocation. LMC itself has developed into a substantial industry, in part because its mathematics are seductively elegant, and in part because it explains patterns that do not have plausible alternative explanations based simply on the mechanics of sex determination. For example, it has often been claimed that the 1:1 sex ratios of mammals and birds are mere side-effects of the X-Y (or Z-W) chromosomal mechanism of sex determination. A recent book by Bull⁶ stands this reasoning on its head, by considering the evolution of a wide range of sex-determination mechanisms, taking into account their effects on the sex ratio.

Wasps have no sex chromosomes, being haplodiploid, so they can play

sophisticated sex-ratio games' involving extreme biases and, more interestingly, conditional responses to local variation in the environment or in the structure of the population. Theorists have explored the strategic possibilities at some length, and experimentalists have tested many of the resulting predictions using laboratory populations of the wasp *Nasonia vitripennis*, which has become the *Drosophila* of sex-ratio research. In no other field of evolutionary biology has it been possible to verify so many detailed quantitative predictions. Recent books by Charnov⁷ and by Trivers⁸ review the work on LMC and on many topics in the theory and practice of sex allocation.

Some of the most exciting recent advances have come not from the laboratory, but from the field. For several years there has been uncertainty as to whether the female-biased sex ratios seen under LMC are responses only to the competition for matings that occurs within groups of brothers, or whether they are also responses to the inbreeding with which such competition is almost always confounded. By comparing three species of fig wasps, Herre has recently shown that the biases reflect both the level of sib-competition and the average level of inbreeding⁹. Theoretical predictions, some derived for the first time by Herre, call for the more highly inbred species to show stronger female biases for any given number of foundresses in an individual fig (that is, for a given intensity of LMC). This is exactly what Herre sees in the three species. Not only are their sex ratios ranked in the expected order, but the actual data fall remarkably close to the theoretical curves relating sex ratio to foundress number. Herre's test of the subtle distinction between inbreeding and LMC was made possible by the existence both of variation within species in the number of foundresses per fig (supplying variation in LMC) and of variation between species in the average number of foundresses per fig (supplying variation in inbreeding levels).

A paper by Yamaguchi¹⁰ on page 460 of this issue also combines advanced theory and field data novel in at least two important respects. First, they add aphids to the list of major animal groups in which LMC appears to cause large sex-ratio biases. This is exciting news, in part because aphids have diploid genetics and chromosomal sex determination. How, then, do they control their sex ratios? The generation of aphids that infest plants throughout the summer are parthenogenic clones of XX females. But at the end of the summer, the last parthenogenic generation produces sexual females (who are XX) and males (who are XO). The male embryos are created by elimination of one X chromosome during a modified mitosis.

A second and strikingly novel pattern seen in Yamaguchi's data concerns sex-ratio differences among females who produce the sexual generation. These found-

Long-running experiments (II)

Although it has sometimes been stopped by mechanical failure, by the need for cleaning or when the ambient temperature has not fluctuated sufficiently, in principle this atmospheric clock has not needed winding since it was built in 1864. Now in the Physics Department of the University of Otago in Dunedin, New Zealand, its mechanism is driven by fluctuations in ambient temperature which expand and contract the air in an air-tight box. It is described in *European Journal of Physics* 5, 195-197; 1984, with a request for other examples of such experiments.

resses differ enormously in total fecundity yet, rather than producing the same proportion of males, each makes approximately the same absolute number. We are not convinced that Yamaguchi's simple and original theoretical explanation for this pattern captures all of the relevant features of the biology of the aphids, as it seems to assume that a female can assess the total fecundity of the foundress group to which she belongs; this would be reasonable for fig wasps, which produce their offspring after arriving at the fig, but may not be reasonable for the aphids studied by Yamaguchi, which produce their offspring before they fly to the trees on which the foundress groups are formed. But the pattern is there. It invites more theorizing and, of course, more empirical work.

XX-XO systems occur in many groups of arthropods and seem often to be associated with complex sex-allocation strategies (as in the laboratory nematode

Caenorhabditis elegans, which is mainly hermaphroditic, but with a small proportion of males). Yamaguchi's data should stimulate a widened search for instances of extreme sex-ratio manipulation among XX-XO species. Aphids themselves are economically important, so it may prove relatively easy to obtain support for studying their sex lives. □

Quantum Hall effect

Dimensionality leaves its mark

from R.J. Haug

WHAT happens when one plays with the dimensionality of an object? This is not an esoteric question of interest only to mathematicians but a very important problem that has been actively explored by solid-state physicists in the past few years, not least because it is likely to lead to many totally new physical phenomena. Already, measurements of a two-dimensional electron gas (2DEG) in strong magnetic fields have revealed the quantum Hall effect (von Klitzing, K., Dorda, G. & Pepper, M. *Phys. Rev. Lett.* **45**, 494; 1980), for which von Klitzing was awarded this year's Nobel Prize in Physics. Now, H.Z. Zheng, K.K. Choi, D.C. Tsui and G. Weimann (*Phys. Rev. Lett.* **55**, 1144; 1985) have found a new, but related, effect — an anomalous variation in the magneto-transport coefficients of a two-dimensional electron gas as the width of the conducting channel becomes smaller than a characteristic length. This is of the order of 10 μm depending on the mobility of the electrons. The authors assume that the effect, which was only observed in high-quality samples, arises from a transition from two-dimensional to one-dimensional behaviour.

One of the reasons for this branch of research is the need for ever smaller components in the electronics industry. But, in addition, the modulation-doped GaAs/AlGaAs heterostructures used by Zheng *et al.* can also be used to fabricate very fast switches (Störmer, H.L., *Nature News and Views* **317**, 20; 1985). One obtains these structures by growing thin layers of GaAs, AlGaAs and AlGaAs doped with silicon on a crystal of GaAs by molecular beam epitaxy (MBE). Because of the

different electronic properties of the two semiconducting materials GaAs and AlGaAs, the electrons from the Si donors in the AlGaAs transfer to the GaAs layer, so forming a quasi-two-dimensional electron gas bound to the interface via the Coulomb attraction of the ionized donors across the junction.

An electron localized in a region of sufficiently small thickness behaves differently from a free electron that is able to move over large distances in all directions. If the electron is confined within a narrow potential well in the third direction, the quantized energy levels become discrete rather than being quasi-continuous. The electrons are unable to move freely in this direction. At low enough temperatures and sufficiently small carrier concentrations all electrons are in the lowest energy level; this is a description of a 2DEG. Owing to the spatial separation of electrons from their ionized parent impurities, the scattering rate is strongly reduced, which leads to exceedingly high mobilities, particularly in the low-temperature regime.

If a strong magnetic field is applied in the z direction perpendicular to a 2DEG kept at the temperature of liquid helium, and the voltages in the direction of the applied current (V_x) and perpendicular to this direction and to the magnetic field (V_y) are measured, a non-vanishing V_y is found in the magnetic field. This is the effect found in 1879 by E.H. Hall at Johns Hopkins University and it is true for all conducting materials. Von Klitzing observed that in a 2DEG at certain regions V_x vanishes, although there is still a current I through the sample and the Hall

voltage V_y shows a plateau. In such regions the relation of V_y to the current I is given by $V_y/I = h/\eta e^2$, where h is the Planck constant, e the charge of an electron and η an integral number.

Zheng *et al.*, like von Klitzing, measured V_x and V_y as a function of the magnetic field at low temperatures, with the aim of investigating size effects in the sample by changing the width of the conducting channel. First, they noticed that the quantum Hall effect is exact. When V_x vanished, the Hall voltage always showed a plateau with $V_y/I = h/\eta e^2$. This is another proof that the quantum Hall effect is a universal property of two-dimensionality of the charge carriers and does not depend on properties of the samples, such as their size.

But Zheng *et al.* also looked at the lineshape of their experimental curves in the region between the plateaus of the quantum Hall effect. When the electrons had low mobilities no difference was observed between wide and narrow samples. But for samples with very high electronic mobilities, the lineshape changed dramatically when the width of the channel was reduced, although the measurements with a wide conducting channel were still comparable to those obtained with low electronic mobility samples.

The data suggest that the new phenomenon arises as the size of the sample approaches some characteristic length of the electronic system. One possible explanation put forward by Zheng *et al.* is that the characteristic length is that of the inhomogeneities in the sample. Another possibility is that it is associated with the electron-electron interaction, in which case the observed effect would have to be attributed to a dimensional crossover from two-dimensional to one-dimensional behaviour. In other words, if the channel is narrow enough the electrons cannot move freely in two dimensions: one direction is open but in the other motion is restricted by the edges of the sample.

These explanations are, however, not definitive. In experiments with silicon metal-oxide semiconductor field-effect transistors (Si-MOSFET), where samples of different channel length but identical channel width have been measured (von Klitzing, K. *et al. Proc. 17th Int. Conf. Physics Semiconductors*, San Francisco, 1984), very long samples produce results that are strikingly similar to those of Zheng *et al.* for very narrow GaAs/AlGaAs samples, whereas short samples do not. For a long sample it is difficult to explain the effect by a dimensional crossover as motion is not restricted in one direction. Nevertheless, the experiments give hints about the underlying fundamental physics. Further experiments and ideas will clarify these problems. □

Cell biology

Organizing the nucleolus

from John Sommerville

THE function of the nucleolus is to produce ribosomes in response to the physiological demands of the cell. Nucleoli develop from chromosomal sites, known as nucleolar organizing regions (NORs), which contain tandemly arranged genes for ribosomal RNA (rRNA). The initiation and extent of their development is subject to both cell-cycle and metabolic influences. At a recent meeting* substantial advances were reported in identifying the components involved in nucleolar activity and in describing the interactions that occur between them.

After mitosis in a cell actively synthesizing proteins, the nucleolus is generated from the NORs as a massive and complex structure, bringing together all of the components required for the manufacture of ribosomes (see the figure). As well as transcription of the rRNA genes by RNA polymerase I under the control of associated transcription factors, this process involves many other components produced in other parts of the cell and brought into the nucleolus. These include about 80 ribosomal proteins, small RNA species required for rRNA processing (U3 and U8 small nuclear RNAs) and ribosome maturation (5S RNA), and several acidic proteins required for the maintenance of nucleolar structure and the assembly and transport of preribosomes. As these components have to be manufactured at a rate determined by the demands of ribosome production, considerable co-regulation of gene transcription is required.

Ultrastructural analysis combined with autoradiography to detect the initial sites of RNA synthesis (G. Goessens, University of Liège) and with selective silver staining to detect DNA- and RNA-associated proteins (K. Smetana, Czechoslovak Academy of Sciences, Prague) has made it possible to map the stages of ribosome formation to distinct regions in the nucleolus. The processes of initiation, production and maturation seem to progress from centre to periphery and the consensus is that the rRNA genes of the NORs are located in regions of low electron density (fibrillar centres), that gene transcription is initiated here but progresses into the surrounding dense fibrillar component where proteins bind to the transcripts, and that processing and maturation of pre-ribosomal particles occur in the cortical granular component.

A key event in initiating nucleolar development at the NOR is the activation of rRNA genes. It has been shown from immunostaining studies (U. Scheer, DKFZ Heidelberg) that substantial amounts of RNA polymerase I are located at NORs during mitosis, permitting rapid activation

of the genes as cells enter interphase. From *in vitro* reconstruction experiments using cloned genes and cellular extracts, the sequence of events in initiating the transcription of mammalian rRNA genes has been established (M. Muramatsu, University of Tokyo). First, a species-specific DNA-binding protein — transcription factor ID (TFID) — binds to the gene-promoter region located just before the transcription start site. A second, growth-dependent transcription factor (TFIA) then acts through protein-protein interactions to bring RNA polymerase I to the promoter. After this initiation complex is formed, both TFID and TFIA remain bound to the promoter region while RNA polymerase I reinitiates many rounds of transcription. It is interesting to note that point mutations at 7, 16 and 25 nucleotides before the transcription start site reduce activity to 0, 10 and 50 per cent of wild type, respectively. This nine-nucleotide interval could represent a linear series of protein contact points along the DNA double helix.

Attraction of transcription factors to promoters in *Xenopus* seems to take a special route (R. Reeder, Hutchinson Cancer Research Center, Seattle). In the spacer regions between rRNA genes, there are multiple 60 or 80 base-pair (bp) enhancer elements, a block of which confers a 20-fold increase in transcription activity compared with genes lacking enhancers. In gene constructs, these elements are effective when they are located 4–5 kbp from the gene promoter; they can be in either orientation and can be located in the gene itself. They seem to function as sites for the attraction and

entry of a transcription factor that is transferred to the gene promoter to form the transcription initiation complex.

Transcription of rRNA genes in *Xenopus* terminates 235 nucleotides beyond the end of the gene (Reeder). Using short DNA probes from this region, a stable RNA species corresponding to this extra transcription is detected, which tallies with electron microscope observations (M. Trendelenburg, DKFZ Heidelberg) of three additional polymerase molecules at the end of the rRNA transcription unit, with no long transcripts attached. It would appear that the rRNA transcripts are rapidly processed by cleavage before transcription terminates. Discovery that RNA polymerase I uses enhancer sequences and 3'-processing of transcripts brings its activities more into line with those of RNA polymerase II.

Of the many proteins that associate with rRNA gene transcripts at various stages of their processing, the best characterized are the ribosomal proteins (rps). Features contributing to the co-regulation of nucleolar rRNA genes and the many *rp* genes scattered throughout the genome have been studied in yeast (W. Mager, Vrije University, Amsterdam), *Xenopus* (E. Beccari, University of Rome) and mouse (K. Dudov, Bulgarian Academy of Sciences, Sofia). The *rp* genes of these organisms are similar in that they often lack a conventional TATA promoter sequence, having instead a long pyrimidine tract running through the transcription start site. In most of 22 *rp* genes in yeast that have been sequenced completely, there are two 12-bp-long homologous sequences implicated in transcription activation, located 300–500 nucleotides upstream of the initiation site.

Co-regulation of the primary rRNA-binding *rp*, L25 has been studied in detail by Mager. By increasing the dosage of L25 genes in yeast cells using a shuttle vector, it is found that L25 transcription is not

co-regulated with endogeneous *rp* genes; instead excess L25 is synthesized, which in turn may block further translation of its own message. A link between nucleolar activity and L25 gene expression is provided by a homologous sequence present in 26S rRNA and L25 messenger RNA, either of which can bind the L25 protein.

The yeast system has similarities with the regulation of expression of *rpL1* in *Xenopus* (Beccari). Accumulation of L1 resulting from an increase in *L1* gene dosage by microinjection into oocytes, leads to blocking of the removal of introns from the *L1* gene transcript. A regulatory sequence is again implicated, here located in the introns of the *L1* gene transcript and in 28S rRNA. Binding of excess L1 to its own gene transcript would effect autogenous regulation by blocking processing and hence further production of L1 until it is removed by binding to rRNA.

In the nucleolus, the predominant proteins are neither transcription factors nor individual rps. Of particular interest are the silver-staining phosphoproteins with relative molecular masses around 100K. Their amino-acid sequences, derived from protein chemistry (H. Busch, Baylor College, Houston) and cDNA sequencing (M. Caizergues-Ferrer, CNRS, Toulouse), contain conserved functional domains. One, rich in glutamic and aspartic acids, is thought to interact with chromatin; another, rich in glycine and dimethylarginine, is found in various RNA-binding proteins. Because they are only transiently associated with rRNA gene transcripts and are lo-

cated in the inner fibrillar regions of the nucleolus, these proteins seem to be involved in relatively early stages of rRNA processing.

A completely different acidic nucleolar protein of 40K (B. Hügler, DKFZ, Heidelberg), associated with preribosomal particles in the cortical granular component of nucleoli and with the nucleoplasmic 65S precursor of the ribosomal large subunit, seems to be functional later. As it is never found outside the nucleus, its primary function seems to be the transport of preribosomal particles. Another important difference is that the silver-staining proteins, together with RNA polymerase I, remain associated with the NOR during mitosis whereas the 40K protein is distributed with some ribosomal protein over the entire surface of the chromosomes. Other nucleolar proteins are distributed into the cytoplasm during mitosis.

Obviously the mechanisms involved in bringing these dispersed components together to construct new nucleoli require much further study. One way into the problem might be to create novel NORs by microinjecting cells with recombinant plasmids containing rRNA genes that would fuse and integrate into chromosomal sites. This approach might also tell us whether intranuclear positioning is important — does the NOR have to be brought into close association with the nuclear envelope before nucleolar development can proceed? □

100 years ago

The fresh-water mussel closes its shell by contraction of two strong muscles — one before and one behind — but how does it open its shell? This has recently been studied by Herr Pawlow. The animal was fixed on a board by one shell, while the other shell was connected by a silk thread with the short arm of a lever — the longer arm of which indicated the movements on a slowly-rotating drum. . . there are two classes of nerve-fibres connected with the muscles — the one motor, producing contractions; the other inhibitory, producing relaxation

From *Nature* 33 106, 3 December 1885

an event that took place in the late Pliocene, 2.3 Myr ago. A search in contemporaneous sediments recovered from the North Pacific sea floor has failed to detect an equivalent siderophile anomaly. Although the exact spatial distribution of the Antarctic debris is unknown, the event was clearly not global in scale, unlike the event thought to have occurred at the Cretaceous–Tertiary boundary.

The estimated infall of meteoritic material in one of the Antarctic cores is about 100 mg cm^{-2} . This rivals the most recent estimate of the average global outfall of meteoritic (chondritic) material of about 140 mg cm^{-2} at the Cretaceous–Tertiary boundary by F.T. Kyte, J. Smit and J.T. Wasson (*Earth planet. Sci. Lett.* 73, 183; 1985). In this core, enrichments in the siderophile element iridium are obviously correlated with the meteoritic material and reach a maximum of approximately 5 ng g^{-1} . This is roughly an order of magnitude less than the maximum values reported for the Cretaceous–Tertiary boundary at Caravaca, Spain. Variation in the relative abundances of siderophiles is a geochemical characteristic of various meteorites and the difference indicates that the Antarctic projectile differed in composition from that postulated to have caused the Cretaceous–Tertiary iridium anomaly.

Because the Antarctic debris is of relatively coarse-grained nature, with particles up to several millimetres in diameter, the type of projectile can be identified with some confidence. Three types of particle have been recovered: vesicular glasses; brecciated and shocked basalt; and Fe–Ni metal. Most of the iridium is in the vesicular particles, which make up more than 90 per cent of the recovered particles and contain about 150–200 ng iridium per gram. The vesicular particles have some textural similarities to meteor ablation spheres but their composition is similar to that of basalt. The identifiable basalt particles consist primarily of the minerals plagioclase and pyroxene and are often enclosed in vesicular material. The basaltic particles could originate either from projectile material or from ocean-floor basalts. Although no chemical analyses are presented, it is clear from the mineral chemistry, particularly the manganese content of the pyroxenes, that they represent material from the group of meteorites termed basaltic achondrites, probably of the howardite type

Meteorites

Siderophile-enriched sediments and meteoritic debris

from Richard A. F. Grieve

Low sedimentation rates make deep-sea sediments a relatively rich depository for the extraterrestrial materials that bombard the Earth. F. T. Kyte and D. E. Brownlee (*Geochim. cosmochim. Acta* 49, 1095; 1985) give details of an important find of meteoritic debris in the Antarctic Basin, which provides evidence that sediments chemically enriched in siderophile elements, those elements that tend to concentrate with iron, are associated with meteoritic material. This discovery, initially reported in *Nature* (292, 417; 1981), clearly demonstrates that large impact events can produce siderophile-enriched sediments, the postulated explanation for the origin of the iridium anomaly found at the Cretaceous–Tertiary boundary.

Siderophile elements, which include

cobalt, nickel, iridium and platinum, occur preferentially with native iron. As a result, they are relatively depleted in the Earth's crust and concentrated in the core. Certain meteorites, however, are relatively rich in siderophiles, and local enrichments in siderophiles have been found in so-called impact melt rocks associated with some terrestrial meteorite impact structures. It had been suggested that siderophile-enriched sediments could also result from the presence of meteoritic material but until now no direct association of siderophile-enriched sediments and meteoritic material had been observed.

The meteoritic material was discovered in two piston cores, recovered from water approximately 5 km deep at sites 120 km apart, at 57°00'S, 89°12'W and 57°47'S, 90°48'W. Palaeomagnetic stratigraphy indicates that the meteoritic debris is from

*The Ninth Nucleolar Workshop, Kraków, Poland, 13–17 September 1985.

This poses a problem. Howardites are differentiated meteorites; that is, their source body underwent large-scale chemical differentiation with the formation of an iron-rich core and a silicate crust. Thus the howardites, which represent the brecciated silicate crust, are relatively depleted in siderophile elements. The basaltic clasts, therefore, cannot be the source of the siderophiles in the vesicular material. The most obvious source is the rare-metal grains. Calculations using a mixing model indicate that the vesicular material could correspond approximately to howarditic material with a 3 per cent metal component. The metal composition required by the mixing model does not correspond exactly to that determined for the cores. This is not, however, a major difficulty, as only one grain was analysed and changes in metal composition caused by oxidation reactions during impact have been documented at terrestrial impact sites.

If the vesicular glasses are a mixture of howarditic material and metal, with a minor addition of seawater, what was the thermal event that led to melting? Heating during atmospheric entry or impact with the ocean are two possibilities. Although they present no compelling arguments, the authors favour the latter. Impact as the heat source is reasonable, at least from the point of view of physics. If impact occurred at 15 km s^{-1} , peak shock pressures would be of the order of 150–200 Gpa, with the attendant post-shock temperature well above the melting temperature of howarditic materials. If the thermal energy

associated with impact was sufficient to produce the vesicular particles, then why are they intimately associated with unmelted basaltic particles? The authors suggest the projectile suffered at least partial break-up in the atmosphere. Smaller pieces would be decelerated by atmospheric drag, so that their impact velocity would be below that required for melting, and would recombine with the melted vesicular material through collisions in the cloud of ejecta. The size of the projectile is poorly constrained at approximately 100–500 m in diameter, on the basis of the distribution of meteoritic material. A projectile in this size range would be subjected to some atmospheric crushing and dispersion, according to the calculations of H.J. Melosh in *Multi-Ring Basins*, 29 (Pergamon, 1981).

From recent calculations of the terrestrial cratering rate, it is estimated that as many as 50 similar events occur in the Earth's oceans every million years. As ocean-floor sampling continues and deep-sea sediments are examined, it is likely that other oceanic impact events will be discovered. This Antarctic discovery not only strengthens the meteoritic origin of the siderophile enrichments at the Cretaceous–Tertiary boundary but, together with potential future discoveries should also provide insights into the complementary subjects of meteoritics and impact phenomena. □

Ecology

Nuclear DNA content as a guide to plant growth rate

from Peter D. Moore

ONE of the most clearly defined aspects of the ecological niche of a plant is the temporal element in its seasonal growth and development¹. Even if all the plants in a meadow are tapping the same energy resource, they can partition that resource in time by expanding their leaf canopies in sequence. A knowledge of such differences can be of considerable importance in the management and conservation of grasslands where decisions must be made concerning the timing of mowing or grazing regimes². As a result of the recent work of Grime, Shacklock and Band³, it is becoming apparent that the timing of the growth of the shoot systems of many grassland plants is closely related to their nuclear DNA content, which means that anatomical examination can provide considerable information about the nature of niche partitioning within a plant community.

Grime and Mowforth⁴ had already suggested that the nuclear DNA content of certain plants is related to the timing of

shoot growth. Having observed that Mediterranean species of plants, which have their main growth periods in winter and early spring, have a high nuclear DNA content, they examined a wide range of British plant species to see whether any relationship between DNA content and time of growth was apparent. The found that species like *Hyacinthoides non-scriptus* (bluebell) and *Ranunculus ficaria* (lesser celandine) that commence growth in the early spring (April) have DNA contents that are about ten times as high as those that commence growth rather late in the season (June), like *Urtica dioica* (stinging nettle) and *Molinia caerulea* (purple moor grass). The capacity to grow at lower temperatures is thus associated with the possession of a large genome.

But the evaluation of the full ecological implications of this proposal required the analysis of an area of vegetation under natural field conditions, which is what Grime and his co-workers have now com-

pleted. They chose to examine the nuclear DNA content of plants growing in a north-facing area of damp limestone grassland in North Derbyshire, England, that was particularly rich in herbaceous plant species. They removed 150 circular turf samples of 10 cm diameter and maintained them under garden conditions, where they were able to establish the rates and times of leaf elongation for all the major species. At the same time they monitored temperature, and measured nuclear DNA content in samples of plants' root tips.

The nuclear DNA contents of the plants was fairly evenly distributed over a wide range from less than 1 pg to almost 40 pg per nucleus. In the cold conditions of early spring (March), species with more than 10 pg DNA per nucleus grew two to four times as fast as those with a less than 10 pg per nucleus. By the beginning of May, the growth rates of the two groups were only slightly different and by June the differences were entirely insignificant.

The experiment clearly demonstrates the limiting effect of temperature on leaf extension in the early part of the year and also the advantage gained in this period by species with a high nuclear DNA content. The authors regard a small nuclear DNA content as characteristic of plants which grow by rapid and continuous cell division during favourable periods (such as the summer season in temperate areas). Rapid spring growth is best achieved by expanding cells which were produced during the previous growing season but which have remained unexpanded during the intervening winter. The problem of conducting mitosis under cold conditions is thus avoided. Such plants characteristically have high nuclear DNA contents. Their growth declines in summer when they conduct repeated cell divisions to produce tissues which will expand during the following spring.

From an ecological point of view, one of the most interesting points to emerge from this work is the chance it offers to catalogue at least one dimension of niche specialization simply on the basis of cytological investigation of the plants in a community. An examination of the spread of DNA values in a community, for example, provides an insight into the extent that the various species are exploiting the range of temporal opportunities available to them.

Now that it has been demonstrated that the broad relationship between DNA content and the time of canopy expansion actually operates in a natural community, it should be possible to make informed predictions about the temporal role of species in various communities on the basis of their DNA content. As Grime and his colleagues point out, DNA analyses may also provide a clue to the vexed question of how certain vigorous community dominants can coexist. For example, the fact that one robust grass, *Brachypodium pinnatum*, has a nuclear DNA content of

2 pg, whereas another, *Bromus erectus*, contains 22 pg per nucleus, may explain the way in which these species partition the environmental resources and thereby manage to coexist. Studies of this kind will assist botanists to appreciate more fully the implications of Gause's competitive exclusion hypothesis in the realm of vegetation. □

Phase transitions in star formation

from Alan P. Boss

MANY dynamical aspects of star formation have become understood through theoretical models of collapsing interstellar clouds but attention has recently been turned to equilibrium models. From models of the possible equilibrium states available to interstellar clouds and their protostellar progeny, it emerges that two types of equilibrium may occur for isothermal clouds with small angular momentum, with one being much denser than the other. Therefore, if there are phase transitions — mathematically analogous to the transition of a Van der Waals gas to a liquid — from the more diffuse to the more compact state, the result could be star formation in clouds that would otherwise be considered stable¹.

An interstellar cloud must contract and increase its density by a factor of about 10^{23} in order to form a star. Observation has yielded little knowledge about the contraction process, because of the inherent obscuration and small length scales involved. Theoretical models of nonmagnetic star formation have focused on solving the exceedingly difficult time-dependent problem of the collapse of an interstellar cloud from an initially unstable state.

Axisymmetrical equilibrium sequences for isothermal clouds with differing amounts of angular momentum, J . No equilibrium exists for sufficiently dense clouds with $J = 0$. Clouds with low J can exist in either a diffuse or compact state, separated by unstable equilibria (broken line). For high J clouds the unstable branch disappears. Phase transitions from the diffuse to the compact branch may initiate star formation (modified from ref. 2).

To include rotation and the possibility of fragmentation, the model must include all three spatial dimensions, a formidable task. Protostellar clouds are effectively isothermal during much of their evolution, but eventually they become opaque and heat up, adding further to the complexity of the computations.

A simpler approach is to seek equilibrium states for rotating, isothermal, axisymmetrical, self-gravitating clouds (see figure). Models based on the global properties of spheroids of uniform density reveal that, for clouds with low angular momentum, two types of equilibrium are possible²⁻⁴: slowly-rotating, nearly-spherical clouds, supported primarily by external pressure (diffuse branch), and rapidly rotating, highly flattened clouds, supported largely by rotation (compact branch). Intermediate configurations are unstable to compression. For clouds with large angular momentum, a single sequence exists, extending monotonically to high densities.

The diffuse state is metastable, because its free energy is higher than the compact branch. The unstable branch has the highest free energy, forming a barrier between the stable branches. If the free energy of a diffuse branch cloud is raised sufficiently, such as by compression in the shock front associated with the spiral arms of our Galaxy, an otherwise stable cloud could dynamically become a compact cloud. Such a phase transition would allow low angular momentum clouds that are stable against collapse to become significantly denser¹.

Phase transitions can only be considered physically possible if detailed models of the two branches can be constructed and shown to be dynamically stable. Rigorous modelling of clouds with external pressure produces stable clouds that become progressively more condensed at their centres as the mass increases⁵. The models become unstable to compression at high central density, as in non-rotating, isothermal clouds supported by external pressure. These models are the realistic manifestation of the diffuse branch³.

Analytical solutions exist⁶. They are compressionally unstable when the cloud is nearly spherical, and dynamically un-

stable to ring formation when highly flattened⁷; intermediate models are stable to axisymmetrical perturbations. However, these solutions are mathematically singular at the origin and extend to infinity. Because of the lack of external pressure, the flattened solutions are similar to the compact branch. Thin-disk models have been constructed which also suffer from an infinite central density, but they do include external pressure. These models are the closest yet developed to a rigorous description of the compact branch. Because compact branch models with finite central density have not yet been constructed, and their stability to axisymmetrical perturbations has not been tested, it is premature to declare the compact branch a possible member of the physical universe. It is important to note that calculations of the dynamical collapse of isothermal clouds have found the diffuse branch⁸ but not the compact branch. Instead, collapsing axisymmetrical clouds produce either rings or runaway disks, depending on details such as the initial distribution of angular momentum.

This discussion has dealt with stability to compressional or axisymmetrical perturbations but interstellar clouds can also distort in a non-axisymmetrical way. Simplified ellipsoidal models form a high angular momentum sequence (similar to the diffuse branch) that terminates when sufficiently compressed. The simplified compact branch models are usually dynamically unstable to non-axisymmetrical distortions which could result in fragmentation and further contraction to the stellar state⁹. The stability of detailed models of the compact state to non-axisymmetrical distortion is unknown.

If phase transitions occur between diffuse and compact interstellar clouds, it may be easier than has been supposed for the process of star formation to be initiated. Clouds that are stable to small perturbations may be hammered into a dynamic collapse towards a denser configuration. A collapsing cloud may well bypass any compact equilibrium state and fragment directly into a protostellar system. The validity of these speculations awaits confirmation of the existence and stability of the compact branch. Bear in mind, however, that unstable equilibrium states are of considerably less interest to nature than to theoretical astrophysicists. □

New strategies for AIDS therapy and prophylaxis

SIR—In search for a reactive agent against HTLV-III/LAV, the virus that causes AIDS (acquired immune deficiency syndrome), the attention is focused on neutralizing antibodies. Such antibodies have been detected in the blood of AIDS patients^{1,2} and form the starting point for the production of vaccines³. However, there are as yet no indications that these antibodies influence the course or the outcome of the disease. Therefore, alternative strategies should be pursued. A recently developed technique for specific inhibition of gene expression provides one possible new way to tackle the AIDS virus. It is based on the inhibition of the messenger RNA translation through the interaction of anti-sense RNA with a specific messenger and in several systems has been shown to be very successful^{4,5}. Accordingly, the introduction of an actively transcribed template for anti-sense RNA of one of the AIDS virus genes into infected cells may induce inhibition of virus replication and increase survival chances of the patient.

The construction of such a template will not be difficult, but how is it to be delivered to the correct target cells? The answer is, in principle, simple. Make a recombinant AIDS virus in which one of the genes is in the reversed orientation. Infection of a patient with this virus will ensure that the recombinant genome is delivered precisely to those cells that are sensitive to, or harbour, the AIDS virus. Cells not yet invaded by the AIDS virus may be protected by the recombinant anti-sense RNA against integration of the AIDS genome. In this way spreading of the virus within the body could be prevented. Which segment of the genome of the virus should be reversed? The *gag* or *pol* regions are unattractive, because the corresponding genes of any helper virus involved in the production of the recombinant might be blocked as well. With the reversion of the *env* gene there is the additional problem that the recombinant virus might acquire the envelope of the helper, resulting in the infection of the wrong target cells. A fourth gene, *tat*, which has recently been identified on the genome of the AIDS virus^{7,8}, is more promising. The gene product is a trans-activator of viral transcription. Preventing the synthesis of the *tat* protein results in a significant reduction of virus replication, which is exactly what we are looking for. In fact, reversion of the second exon of the *tat* gene, which is located between *pol* and *env*, would alone be sufficient.

In theory, the only problem that we are left with is the efficient production of the recombinant virus, because this may require the action of the *trans*-activator protein. A cell line producing and accumulating the *tat* protein in sufficient quantity, prior to infection with the recombinant

virus, might be effective. Now that the sequence of the gene is known such a cell line is within reach. Alternative methods can be thought of, one of which is to load cells before infection with the *tat*-protein, obtained from any source, by the method of scrape loading⁹, which works well especially with proteins of small size.

Although problems would surely show up during the development of the strategy outlined above, AIDS is too serious a threat to human life to let any possible means for therapy and prophylaxis go untested. The method might also be tried for other diseases, including the T-cell leukaemias caused by HTLV-I and -II.

SIR—We wish to suggest a gene therapy scheme for the control of acquired immune deficiency syndrome (AIDS). The current view on AIDS is that infection with HTLV-III/LAV virus, tropic for OKT4⁺ lymphocytes, results in breaking the backbone of the immune system. The diversity of viral strains and the nature of the infection renders problematic the production and use of vaccines¹. A strategy has been proposed consisting of "protecting" T-cell clones against HTLV-III by using viral interference through infection with attenuated virus².

In our view a better way to achieve this protection would be through the strategy of antisense RNA. Inhibition of gene expression has been achieved in a variety of systems with as little as 52-base-pair, homology to the 5' untranslated segment of the sense RNA³. Helper-free, defective HTLV-III, containing the appropriate group-specific inverted viral gene segments could be produced in a packaging cell line modelled on the Zipneo-ψ2 system⁴. To ensure out-titration of sense-RNA, a gene amplification system, such as the DHFR gene responsive to the anticancer drug methotrexate, could be built into this antisense virus⁵.

AIDS therapy would consist in removal of bone marrow stem cells from patients, followed by their infection with the anti-virus and reinsertion, resulting in the production of "protected" lymphocytes. Alternatively, peripheral blood lymphocytes obtained by pheresis would be infected and reinserted. Methotrexate induced amplification of the antisense provirus may be carried out in vitro, as needed⁶. By these means a critical and sufficient population of T cells might be protected so that an effective immune

response against all strains of HTLV-III and against opportunistic infections could be achieved.

Cerebral supermanifolds and little brains

SIR—John Marshall's analysis of current neuropsychological efforts to correlate specific lexical dysfunctions with "focal" brain damage raises, expectedly, some presently unfocused issues: (1) The "focal" brain damage reported by Hart *et al.*¹ was a "left-hemisphere cerebrovascular accident" diagnosed by computerized tomography as "an infarction involving the left frontal-lobe and basal ganglia." This is, by cerebral neuroanatomical criteria, a truly enormous, almost global region of damage.

(2) Marshall's interesting quotation from Johann Gesner² suggests that even the classical eighteenth century allowed speculation about the validity of linear transformations from a 'psycho'-logical to a cartesian frame of reference in cerebral cortex.

(3) Despite some rough approximations to a two-dimensional somatotopy found in mammalian and primate somatosensory-specific cortex (for example, the primate digit and mouse whisker-barrel "representations"), we have no reason to suppose a linear two- or three-dimensional mapping of inner and outer spacetime to exist inside our heads. Since the days of Maxwell to Einstein would it not be more reasonable to use differential geometry in our approach to understanding how brains might work? A start has already been made for our "little brains".

ADVANCES IN INFRARED AND RAMAN SPECTROSCOPY, Volume 12

edited by **R.J.H. Clark**, *University College, London* and **R.E. Hester**, *University of York*

The major objectives of this well-established series, presenting critical review articles in fundamental and applied infrared and Raman spectroscopy, are to integrate theory and practice and to bring together the different branches of research in both the academic and industrial spheres. The papers commissioned cover a wide range of subjects where progress has been recent or is expected in the near future, and reflect the wide application of these techniques in the science and engineering fields.

Series: *Advances in Infrared and Raman Spectroscopy*, Volume 12

A Wiley-Heyden publication.

MODERN PRACTICE OF GAS CHROMATOGRAPHY, Second Edition

edited by **R.L. Grob**, *Department of Chemistry, Villanova University*

The same nomenclature guidelines as in the previous edition have been followed, and the discussion on columns has been expanded to three chapters: the packed column, capillary column technology and optimization of separations in GC. These latter two topics have become very important since the publication of the first edition. The application chapters have been modified and several new chapters have been added — for example, petroleum and petrochemicals, polymers and environmental applications.

LABORATORY RAMAN SPECTROSCOPY

by **D.P. Strommen**, *Carthage College* and **K. Nakamoto**, *Marquette University*

This book presents a "nuts and bolts" approach to using Raman Spectroscopy and recording Raman data. It serves as a laboratory reference manual for both novice and expert chemists, with procedures and appropriate cautions carefully explained. It includes tables of laser frequency, plasma lines and calibration procedures as well as a listing of sampling techniques.

0471 81323 0 146pp March '85 £31.15

ANALYSIS OF ORGANIC AND BIOLOGICAL SURFACES

edited by **P. Echlin**, *University of Cambridge, UK*

This is a first time compilation of unrelated methods useful in the analysis of organic surfaces. Specialized chapters treat the nature and use of techniques, compare methods of analysis, examine the advantages and disadvantages of particular methods, describe applications, and provide a list of key references.

HANDBOOK OF TRITIUM NMR SPECTROSCOPY AND APPLICATIONS

by **E.A. Evans**, and **D.C. Warrell**, *Amersham International, Bucks*, **J.A. Elvidge**, and **J.R. Jones**, *Department of Chemistry, University of Surrey*

This book is primarily a handbook for those scientists interested in using tritium NMR spectroscopy. It covers the development and use of the technique, which is the only non-destructive method available for the routine determination of labelling patterns in tritium labelled compounds, essential tools for research in the life sciences. The book highlights the uses of the technique not only for determining the positions of labels but also in understanding catalysed hydrogen isotope exchange reactions, the function and mechanism of action of catalysts, reaction mechanisms and isotope effects.

0471 90583 6 264pp May '85 £25.50

TOPICS IN CARBON-13 NMR SPECTROSCOPY, Volume 4

edited by **G.C. Levy**, *Syracuse University*

This fourth volume summarizes many of the exciting developments taking place in the field of carbon-13 NMR spectroscopy. Emphasis is on experimental methods with some material of theoretical interest. Chapters include shimming procedures on superconducting solenoids. Ultra High Frequency ¹³C NMR, how to do accurate spin relaxation measurement and much more.

PRACTICAL ORGANIC MASS SPECTROMETRY

by **J.R. Chapman**, *Kratos Analytical Instruments Ltd*

Providing the first up-to-date, detailed description of the newer techniques now available in organic mass spectrometry, this book begins with a general introduction to the subject, which is followed by a series of chapters devoted to specific practical techniques in organic mass spectrometry. Theoretical aspects are covered only in so far as they are relevant to the practical applications of the technique discussed.

From Academic Press

HANDBOOK OF PROTON-NMR SPECTRA AND DATA

Edited by Asahi Research Center, Co., Ltd.

Academic Press is pleased to present the publication of five new absorption spectrum data handbooks on the Proton Resonance (P-NMR) of organic compounds.

While other P-NMR spectra chart books are available, they are based on the use of outdated spectrometers with lower resolving power and lack spectra on novel and potentially useful organic compounds that have been found through recent research and scientific developments. Most of the measurements in HANDBOOK OF PROTON-NMR SPECTRA AND DATA have been made with the currently preferred 90 MHz FT-NMR spectrometers but measurements for novel and potentially attractive compounds, as well as for natural compounds that are required for analysis of finer structures, have been made with resolution spectrometers as high as 400 MHz.

1985, 5 volumes, 4000 charts (800 per volume) / 60 index pages per volume (average)

Available only as a five volume set. \$880.00 / £770.00

Feathered wisdom

Freeman J. Dyson

Hawks, Doves and Owls: An Agenda for Avoiding Nuclear War.

Edited by Graham T. Allison, Albert Carnesale and Joseph S. Nye, Jr.
W. W. Norton: 1985. Pp. 282. \$14.95, £12.95.

THIS book has been edited by three pillars of the Harvard establishment who have long experience as expert advisors to the American government. They have produced an introductory chapter and two summarizing chapters. In between are six chapters written by others, discussing in greater depth six particular contexts within which nuclear war might arise. Each is a scholarly analysis, full of historical facts and supported by numerous footnotes. The book as a whole is readable and tells a coherent story without becoming repetitious. Its main emphasis is put on confusion as the most likely cause of nuclear war.

The longest chapter is also the most informative. It is "Soviet Perspectives on the Paths to Nuclear War," by Stephen Meyer, director of the Soviet Security Studies Working Group at MIT. Unusually, for an American discussing strategic questions, Meyer has paid careful attention to what the Soviet military authorities say and do. Half his extensive footnotes refer to Russian-language sources. But more than this he says: "Let me begin, then, by noting some sources not used in this chapter. First in this category are official Soviet pronouncements on military doctrine and policy . . . A second source not used is the work of Soviet academics . . . This chapter's sources include Soviet military planning literature, Soviet military historical analyses, Soviet diplomatic behavior, Soviet military force structure and deployment data, and memoir material." Most of us amateurs who claim to know something about Soviet attitudes collect our impressions from the two sources which Meyer discards as unreliable. His conclusions are firmly based and not proffered where evidence is lacking.

Meyer's description of Soviet attitudes emphasizes the Soviet doctrine of pre-emption. He does not overlook the inconsistencies between the formal 'no-first-use' policy enunciated by Brezhnev and the practical reliance on pre-emption which is visible in Soviet operational planning. The inconsistencies will not be quickly or easily resolved. We see a clear recognition by the Soviet military that decisions on the use of nuclear weapons are restricted to the supreme political authorities, and we see military plans which take the political decisions for granted.

Meyer believes that in an acute crisis the military plans are likely to prevail. The

most serious danger of nuclear war would arise from a Soviet decision to launch a pre-emptive attack in response to a sudden and panicky mobilization of NATO forces at a moment of crisis. He regards as particularly unwise the American habit of putting nuclear forces on world-wide alert as a signal of political resolve. This was done during the Cuban crisis of 1962 and the Egyptian crisis of 1973, in both cases without causing disaster. If it is done again in a future crisis arising closer to Soviet territory and appearing to threaten Soviet vital interests, disaster may be more difficult to avert.

Another good chapter is "Escalation in Europe" by Fen Osler Hampson, a Harvard post-doctoral fellow. One of Hampson's important suggestions is that, in case of serious fighting in Europe or in the Middle East, the escalation to nuclear war may happen more easily at sea than on land. Naval units on both sides have a freer access to nuclear weapons than land units, and the political controls at sea are looser. At sea there is an abundance of tempting targets for nuclear weapons, and the absence of civilian populations from the battlefield makes it easier for the warriors to yield to temptation. For all these reasons, the nuclear weapons at sea are more likely than those on land to get us into an unintended nuclear war.

There is an outstanding opportunity for us here to lessen the risk of nuclear war by extending and reinforcing the American-Soviet Incidents-at-Sea Agreement of 1972. The Incidents-at-Sea Agreement has two main components. It formulated an agreed set of rules for regulating traffic

in areas such as the Mediterranean where the two navies are apt to encounter each other frequently. And it established a joint commission of American and Soviet naval officers who meet twice a year to discuss dangerous incidents and to revise the rules when necessary. The holding of regular and quiet meetings between military officers is perhaps the most useful immediate step we can take to decrease the probability that local crises will escalate to general war. There is no reason why similar meetings should not be held by armies and air-forces as well as by navies.

The final summary by the editors is divided into two parts. First they give us an analytical framework for thinking about nuclear strategy; then they tell us what to do. The framework is based on the three ways in which people are afraid that a nuclear war might begin. War might begin because national leaders are weak and irresolute in standing up to aggression, or because they are paranoid in reacting to imagined or exaggerated threats, or because they are confused and unable to control events at moments of international turmoil. People who are most afraid of weakness are hawks. People who are most afraid of paranoia are doves. People who are most afraid of confusion are owls. The editors remark that all three fears are well justified by the evidence of past history and present realities. Hawks, doves and owls are all speaking truth.

A rational strategy must deal with all three fears simultaneously. What to do, is a question of balance and emphasis between the three dimensions of danger. The debate until now has been largely between hawks and doves, and has for that reason become ideological and impractical. The editors seek to redress the balance by giving major emphasis to the concerns of the owls. One of the wisest of the owls is William Ury, whose recent book *Beyond the Hot Line* gave us a number of sensible suggestions to mitigate the dangers of war arising from accident, incompetence and panic. Although Ury is not one of the present authors, his ideas are plainly visi-

High tension — the USS Barry steams alongside the Soviet freighter Anosov off Puerto Rico during the Cuba crisis of 1962. Could we now cope better in such a situation?

ble in many of the chapters. He was a member of the Avoiding Nuclear War Project out of which the book grew.

The final list of recommendations is divided into ten sections. Two of the sections are hawkish, two are dovish and six are owlsh. These proportions reflect the editors' belief that at present the dangers of war through weakness or paranoia are over-rated and the dangers of war through muddle are under-rated. The majority of their recommendations are directed toward avoiding a nuclear version of the outbreak of war in 1914, an outbreak driven by geographical and historical accident rather than by any grand design.

A small sample may indicate the general flavour of the editors' recommendations. I choose five that I consider characteristic, one hawkish, "Don't adopt a No-First-Use policy." one dovish, "Don't assume that nuclear deterrence will last forever," and three owlsh, "Do reduce

reliance on short-range theater nuclear weapons, do work with the Soviets to prevent and manage crisis, do encourage non-governmental contact with the Soviets." It is not necessary to agree entirely in order to applaud the clarity of their thinking and the brevity of their style.

I happen to disagree strongly with their No-First-Use recommendation, and still I recommend their book whole-heartedly as a fair and lucid statement of the nuclear dilemma. Only one essential thing is absent from their world-view. They lack a sense of the absurd. It may be that a resolution of the nuclear dilemma will come in the end from a general recognition of its absurdity. I would like to add one more recommendation to their list, "Don't take nuclear weapons more seriously than they deserve." □

Freeman J. Dyson is in the Institute for Advanced Study, South Olden Lane, Princeton, New Jersey 08540, USA.

Manual works

Graham Richards

A Handbook of Computational Chemistry: A Practical Guide to Chemical Structure and Energy Calculations. By Tim Clark. Wiley: 1985. Pp.332. £35.80, \$35.

Semi-Empirical Methods of Quantum Chemistry. By Joanna Sadlej. Ellis Horwood: 1985. Pp.386. £47.50, \$71.25.

COMPUTATIONAL chemistry has come out of the closet. No longer is the calculation of molecular conformational energy or electronic distribution confined to a small clique of tolerated but mildly deviant academics who scorn conventional experimental practice. Even in the staid halls of industry, theoreticians are now to be found working alongside straight organic chemists, designing novel compounds with the aid of calculations — both quantum mechanical and of the molecular mechanics type — and, increasingly, assisted by sophisticated computer graphics displays.

This growing army has a real need for a handbook which details not the theory behind the methods used, but rather where to start and how to use the program packages available. The most favoured weapons currently in use for elucidating conformation are programs based on molecular mechanics (treating molecules as balls and springs with empirical force fields). These are supplemented with molecular orbital calculations to unravel the electronic details, with the semi-empirical methods known by the acronymic titles MINDO, MNDO and MOPAC becoming standard, together with variants on the *ab initio* molecular orbital method developed by Pople and his co-workers (currently known as GAUSSIAN 82).

The use of all these packages requires

the chemist to present as input the geometrical structure of the molecule under consideration. Clark's excellent manual provides clear and detailed instructions on how to submit data for the most widely adopted packages. It is replete with examples of sample input and of output, just the thing to enable an experimental chemist to be able to use the available programs. The book does not provide much about the general background theory, nor does it underline the rather shaky theoretical basis for some of the methods (these matters are, however, discussed in many, more conventional textbooks on theoretical chemistry). Instead we have a very practical manual, the review copy of which has already been tested by novice graduate students with happy results. The theoretical section of chemistry bookshelves is generally overstocked, but this book fills a genuine gap and will undoubtedly be found at the elbow of many users of packages.

Sadlej's text is in an overlapping area and is a more conventional account of the semi-empirical methods of quantum chemistry: sadly it is the book one wanted ten years ago. The Polish edition was written in 1976 and although "revised", the age shows. The bibliography goes up only to 1978, and the techniques upon which the book concentrates — the Hückel method and CNDO — are both now somewhat *passé*.

Those theoretical chemists who resent the loss of their exclusive and even furtive world will no doubt grumble that running a computer package no more makes one a theoretician than sleeping in a garage makes one a mechanic. But computational chemistry is on the rise and life should be made easier for the virgins. □

Graham Richards is a lecturer in the Department of Physical Chemistry, University of Oxford, South Parks Road, Oxford OX1 3QZ, UK.

Cool side of life

Pierre Douzou

Biophysics and Biochemistry at Low Temperatures. By Felix Franks. Cambridge University Press: 1985. Pp.210. £25, \$44.50.

ALTHOUGH Felix Franks in a sense is correct in his forward "cold is the fiercest enemy of many forms of life", biologists dream of exploiting it for the cryopreservation of "spare parts" of living systems amongst other problems. Like physicists some decades ago, biologists are becoming increasingly interested in the measurement, interpretation and exploitation of natural phenomena at low temperatures, and cryogenic research is slowly becoming a branch of this discipline. Franks' book is a step along the way in this endeavour.

The book gives clear answers to the classical questions about the physics and physical chemistry of water at sub-zero temperatures, the effects of its behaviour on life, and current applications in biochemistry. Other specialized chapters survey our understanding of the responses of the cell and of living organisms to cold, and of the problems of their preservation in the laboratory, a problem still dominated by empiricism and clouded by the interplay of an extraordinary variety of factors. The book ends with a survey of future prospects in this challenging but promising field.

Franks has been a leading contributor to research on water structure and properties, here he combines this expert insight with his interest and recent experience in cryopreservation for the task of explaining what is known and what is uncertain, and of suggesting what can be done to set up a useful cryobiology. The writing of a book on this topic demands a grasp of many specialized fields and is a daunting task, but the result here is agreeable and very instructive, because the book reveals its origin as a lecture course by a man trained as a physical scientist who drifted into the life sciences "fairly late in life and [who] never received any formal teaching in biological dogma" and had first to teach himself.

The book gives a strong impression of unity, carries with it a tone of optimism and in some cases of certitude and is valuable in that it covers a range of subject material which has never before been brought together in such an organized and concise yet clear manner. It will be of great interest to that growing band of researchers working on the cryobehaviour of living organisms. □

To win friends and influence people

Ian Stewart

The Elements of Graphing Data. By William S. Cleveland. *Wadsworth:1985.* Pp.323. Hbk \$27.95, £37.80; pbk \$18.95, £25.60.

"In 1980," says the author, "I began a study of graphs in scientific publications . . . In one study, I read the articles and reports of the 1980 Volume 207 of *Science* . . . 30% of the graphs in the volume had at least one of four types of specific problems." Those problems were: something on the graph but not explained, parts of the graph being visually indistinguishable, and mistakes such as mislabelling or poor reproduction. Deeper problems included poor choice of the form in which to present the data, and indeed poor choice of data. In an effort to combat these problems, and to suggest effective counter-measures, this book discusses the principles and methods of graphical construction, amply illustrated by examples selected from the literature (with references, which may lose the author a few friends but makes the arguments more cogent).

Scientists spend a large part of their training learning how to do science; and very little learning how to communicate it. Perhaps this is unavoidable, especially given the pressures of crowded curricula; possibly it would make little difference if students attended the odd course on good presentation and effective data display. But, at the very least, they could be encouraged to read a book such as this. Once sensitized to the pitfalls, they might be more prepared to put in the effort required to select a clear and effective means of presenting their results.

Consider even the most standard type of graph, with two axes, some tick marks

to show the scale, dots for the data, and lines connecting the dots. Do the data stand out, or are they obscured by the connecting lines? Do the data points overlap and obscure each other? Do the axes fall across data points? Are there too many tick marks? Do the labels clutter the picture and make it hard to grasp the significant features of the data? All these matters require proper attention. Other types of graphical medium, such as the scatterplot, pose other questions.

One especially fraught area is the display of multidimensional data. To graph the relations between ten or twelve different variables can stretch even the most active imagination. Most attempts fail in one way or another. The author suggests the use of colour to improve readability; this is fine in principle, but most journals refuse to include colour because of its cost. The scatterplot matrix — an array of coordinated plots of all possible pairs of variables, one against the other — manages to convey a great deal of information succinctly and clearly.

The danger with principles is that they can be taken too literally. A few horrific examples show what happens when the Darrell Huff Dictum, "always include zero in the scale", is overdone. To cramp the data into a tiny corner of an otherwise blank graph helps nobody. Huff was thinking more about advertising or political propaganda, and when preparing a graph for scientific publication, it should be permissible to assume that the reader has the intelligence to read the numbers on the axes.

If you're not willing to present your data effectively, then presumably you don't really care what they are. If you don't write papers that others can read, why write papers at all? The author's basic message is a simple one: remember that the important thing is the data. Granted this, all else will follow. □

A look around the kitchens

Alastair Hay

Controlling Chemicals: The Politics of Regulation in Europe and the United States. By Ronald Brickman, Sheila Jasanoﬀ and Thomas Ilgen. *Cornell University Press:1985.* Pp.344. \$38.45.

EARLY attempts by some United States Government Agencies to control the availability and use of chemicals were derided by critics, and the chemical industry in particular, as "cook-book" approaches to the subject. Fifteen years later things have changed, but analogy with cooking remains an appropriate way to describe the thesis of this book.

The authors have set out to compare how chemicals are regulated in Britain, West Germany, France and the United States. It is as if four cooks were asked to bake a loaf of bread — starting with the same ingredients, they follow different recipes but end up with a loaf nevertheless. The European cooks keep their techniques to themselves, arguing that their success lies in some secret mix. The American, on the other hand, has an audience to scrutinize all the ingredients, check the recipe and follow each step from mixing to baking.

The same applies to chemical regulation. Europeans prefer a consensus approach, negotiating with interested parties behind closed doors and presenting final versions of regulations which are rarely altered by Parliament. In the United States, however, the procedure is adversarial, with the government, Congress, the courts, public interest groups and industry all having a say in the matter.

While recognizing that the European pattern of involvement is more restrictive, the contention of Brickman and his colleagues is that, despite this lengthy and expensive process, legislation in Europe is as — or more — effective as that in the United States. (To prove the point, a comparative table of regulated substances is appended to the book, showing limits for the four countries.) Their conclusion is drawn from a thorough analysis of the European systems, some features of which, they argue, could well bear consideration by both regulators and legislators in the United States.

There are fundamental differences between the regulatory processes applied in Europe and the United States. Where the scientific evidence on the hazards — and the carcinogenic risk in particular — of a chemical is unclear, the Europeans tend to adopt a policy of 'innocent until proven guilty'. In the United States, however, guilt is assumed, until proven otherwise, and decisions about regulations are made from that standpoint.

The resolution of this graph is degraded by the inclusion of zero on the vertical scale.

Brickman *et al* point out that "concepts like 'reasonable' and 'practicable' sum up British regulatory philosophy, a philosophy generally shared by industry". Discussions about what these terms mean as far as particular chemicals are concerned are carried out in private between civil servants and industry. In the case of decisions taken by Britain's Health and Safety Executive, workers' trades unions are also involved. The result, say the authors, is usually a compromise that all sides are prepared to live with.

On the question of whether there is a 'safe' concentration for carcinogens to which workers can be exposed without risk, Britain seems to be out of step. British regulators, are favourably disposed to the concept of a threshold. As pointed out in the book, a guidance note issued by the British Health and Safety Executive in 1978, proposed a method of determining a "practical threshold of neoplastic response" while conceding that a "precisely defined" threshold cannot be attained. But Britain, it seems, is the only country that has banned some chemicals in the workplace because of their carcinogenic properties.

In Germany, the analysis of hazards is usually carried out by scientific advisory committees within each Ministry, who then also support appropriate regulations. It appears that these committees have a similar philosophy to the US Agencies in that they accept that there is no safe

threshold level for carcinogens. Because the German Commission on hazardous substances in the workplace argues that there is no way of assessing a threshold and calculating a tolerance level, this leaves the Federal Labour Ministry free to set exposure standards for carcinogens at any level it regards as economically and technically feasible. Similarly, the French are reluctant to establish threshold limiting values, and the strategy for regulating carcinogens is to "combine strict medical monitoring with reporting and personal hygiene requirements".

In the United States, however, legislation is preferred. But the strict standards for chemicals in the workplace recommended initially by Regulatory Agencies are invariably toned down by a process of attrition in the courts. The end result of this is standards similar to those in force in Europe.

While the author's principal conclusion is the need in the United States for a more uniform approach to rule-making, and an opportunity for more negotiations between competing interests, they do not envisage less information on chemical hazards being released to the public (something which would win widespread approval in Europe). It is ironic that at the same time that some Americans are recognizing the benefits of toning down their procedures, many Europeans are starting to see merit in a system of greater accountability — that is, they would like more people to be let into the kitchen. This well-researched and well-argued book will be an excellent starting point for people of both persuasions. □

Get together

Marie Boas Hall

Science Reorganized: Scientific Societies in the Eighteenth Century. By James E. McClellan III. *Columbia University Press*. 1985. Pp.413. \$38.50, £41.80.

To join with others in a more or less formal group seems a natural human instinct of modern society. European scholars have long done so, in forms conditioned by the state of society: in the Renaissance under noble or princely patrons, later as a subsidiary of centralized monarchies, later still as a manifestation and a reflection of emergent nation-states. The first resultant academies were mainly literary or musical or scholarly; as science developed in the seventeenth century its practitioners drew together, either by correspondence or by association, and scientific academies, institutes and societies were born. And it is the societies and organizations themselves that form the focus of Dr McClellan's book.

Of these emergent academies the Royal Society of London (founded 1660, chartered 1662) and the Académie Royale des Sciences of Paris (1666) are the oldest in continuous existence, although not the first to be conceived. Both differed from earlier foundations in being independent of a private patron, in being incorporated entities and in publicizing the work of their members. The Académie (itself parallel to the Académie Française of 1635) was the prototype of modern national institutes and academies, its members paid by and sometimes appointed by the state, while the Royal Society was and is independent of the Government, though adviser to it and an agent of it.

Until roughly 1730 the Royal Society had the more eminent members and hence the greater reputation; slowly, in the wake

of reform in 1699, the Académie reversed the situation. Because of this and the fact that French culture and politics dominated eighteenth-century life in continental Europe, later academies were imitations of that of France, until Berlin, St Petersburg (both initially mainly consisting of foreign savants), Uppsala, Turin and a host of provincial cities all possessed formal organizations with charters, publications and paid members. These were sometimes purely scientific, sometimes, especially later in the century with growing linguistic nationalism, combining a scientific with a parallel literary section, while England, after the growth of private provincial societies, about 1790 saw the rise of the "Lit. and Phil." movement.

What was the cause of all this activity? Dr McClellan as he surveys the eighteenth-century scientific academy sees it as the result of increasing professionalism in science (he does not discuss non-scientific groupings). He is interested in the organizations, which he describes and analyzes fully, not in the individuals who made them up nor, except where cooperation between societies was involved, in the work they accomplished. This gives a lack of solidity to his account, reinforced by a certain naivety about European (including English) history, pointed up by the American sections. (Nor has he a very sharp grasp of language.) He is at his best in describing the structure of the new continental European academies and the relationships between them and he rightly regards as innovative the beginning of a formal (as distinct from a personal) exchange of publications begun in mid-century. There is a very great deal of information in this book which clearly shows how scientific academies developed during the eighteenth century. □

FOURIER TRANSFORM NMR SPECTROSCOPY

Second Edition

DEREK SHAW, *IGE Medical Systems Ltd., Slough, Berks., UK*

Studies in Physical and Theoretical Chemistry 30

A comprehensive guide to the theory and practice of NMR spectroscopy in its many forms, this is the revised, updated edition of the book published in 1976. At least 25% of this new book is new or heavily rewritten. It presents the whole range of Fourier Transform NMR techniques, including 2D NMR and NMR imaging. Containing a wealth of information on techniques and methods, it gives the reader a sound base from which to apply Fourier NMR techniques to many areas of science where they are proving of most value.

INORGANIC ELECTRONIC SPECTROSCOPY

Second Edition

A.B.P. LEVER, *York University, Downsview, Toronto, Ont., Canada*

Studies in Physical and Theoretical Chemistry 33

Required reading for all post-graduate students, post-doctoral fellows and other research workers with interests in transition metal electronic spectroscopy, this is the book in the field. An extensively revised edition of the book which first appeared in 1968, it contains a wealth of new material and gives up-to-date, detailed coverage of the electronic spectra of inorganic systems.

July 1984 878 pp. US \$ 101.75/Dfl. 295.00 0-444-42389-3

INDUCTIVELY COUPLED PLASMA- ATOMIC EMISSION SPECTROSCOPY

An Atlas of Spectral Information

R.K. WINGE, V.A. FASSEL, V.J. PETERSON and M.A. FLOYD,
Ames Laboratory, Iowa State University, Ames, IA, USA

Physical Sciences Data 20

This is the only compilation of spectral data to give the analyst a general view of the elemental spectra emitted by the inductively coupled plasma. The comprehensive treatment enables one to assess the relative liabilities of prominent analytical lines to interferences from molecular bands, recombination continua, and certain classes of spectral line overlaps.

MASS SPECTROMETRY IN THE HEALTH AND LIFE SCIENCES

Proceedings of an International Symposium, San Francisco, California, USA, September 9-13, 1984

A.L. BURLINGAME and NEAL CASTAGNOLI, *University of California, San Francisco, CA, USA (editors)*

Analytical Chemistry Symposia Series 24

This volume provides a state-of-the-art overview of recent discoveries and new methods in the field of mass spectrometry. Attention is specially focused on labile biochemical and biological compounds for which "classical" mass spectrometric methods were not or less suitable. A large number of the chapters in this book deal with applications of newly developed techniques in such areas as biological chemistry, clinical research, molecular design etc.

Research Conference on Familial Cancer, Basel, September 1985
Editors: H. Müller; W. Weber, Basel
XX + 292 p., 37 fig., 66 tab., hard cover, 1985
SFr. 185.- / DM 222.- / US \$ 78.75
ISBN 3-8055-4245-3

The observation that certain cancers tend to cluster in families has focused attention on the importance of inherited susceptibilities in the development of malignancy. Based on an international conference, this volume provides a state-of-the-art account of current efforts to understand both the incidence and significance of familial cancers.

Featuring 78 succinct reports and summaries of discussions, the book provides a source book of new concepts and data useful for all oncologists, medical geneticists, genetic counselors, and physicians involved in the diagnosis and treatment of malignancies.

THE DEVELOPMENT OF A MEDICINE

R. B. SMITH

A highly readable account of an area which is of vital interest to the medical profession and the public alike.

The Development of a Medicine places the discovery and development of medicines in a historical context and then explains the extremely complex and lengthy process by which a drug or medicine is developed from the laboratory bench to availability for prescription by the physician.

After twenty years' research and clinical work in medicine and pharmacology, R. B. Smith is now a consultant to the pharmaceutical industry.

Part 2. The participating astrologers were separately given the natal chart of a random subject and an objective and respected measure of his personality traits called the California Personality Inventory (CPI). They were also given two other

Fig. 2 A typical CPI profile.

CPIs chosen at random from the group of all the subjects' CPI test results. The astrologers were then asked to select the two CPIs (first and second choice, no ties allowed) which described personalities closest to the personality indicated by the natal chart. They also rated each CPI on a 1-10 scale (10 being highest) as to how closely its description of the subject's personality matched the personality description derived from the natal chart. The scientific hypothesis predicts a correct choice one third of the time; the astrologers predicted a correct choice half the time or more.

The two parts of the experiment are complementary; the first is not sensitive to biases in the CPI, the second does not make the possibly false assumption that subjects can accurately judge their own personalities. We decided at the outset to require a 2.5 standard-deviation increase over random chance to interpret the results as favouring the astrological hypothesis. Similarly, a disagreement by 2.5 standard-deviations or more would be required to reject the astrological hypothesis in favour of the scientific one. Otherwise, we decided in advance, we would draw no conclusions of significance. No data were analysed until all the data had been collected.

Experiment design

To eliminate bias, both anticipated and unknown, we made extensive use of double blind techniques. All subjects were assigned a five-digit random code number. Neither the astrologers nor the experimenter knew what code number corresponded

to which person. These lists were solely under the supervision of Richard A. Muller, Professor of Physics at the University of California, Berkeley.

Guidance was sought both from the scientific and astrological communities. To help ensure correctness of the testing method and statistical analysis, the scientific adviser was Professor Muller. So that participating astrologers should be respected by the astrological community, we sought the advice of the National Council for Geocosmic Research (NCGR), an organization which has been involved in much astrological research in the past and which has the respect of astrologers world wide; NCGR nominated persons who consented to be our astrological advisers, and who carefully reviewed the experimental design and made many suggestions.

After they were satisfied that the experiment was a 'fair test' of astrology, our astrological advisers established their predictions (50 per cent for both part one and part two) as the minimum effect they would expect to see. They also compiled a list of approximately 90 astrologers with some background in psychology who were familiar with the CPI and held in high esteem by their peers. It was the opinion of the advisory astrologers that a random sample from this list would be able to score at the predicted 50 per cent level. All were invited to participate; 28 accepted. (Only two astrologers who participated were not on the original list. They heard of the experiment and wanted to take part. After their qualifications had been vouched for by NCGR, they were admitted.)

Constructing a natal chart is a simple but laborious mathematical process, so computers are well suited for the task; several machines designed specifically for this purpose are available on the market. To save time and ensure accuracy, all natal charts were constructed by Mr. Caveney (President of the San Francisco chapter of NCGR) and Mr. Nelson (Secretary of the San Francisco chapter) on a Digicomp DR 70 Astrological Computer; they were spot-checked by hand calculation.

The California Personality Inventory (CPI) is a standard personality test¹⁻³ which has been used extensively since 1958. It was chosen over other available personality tests because the advising astrologers judged the CPI attributes to be closest to those discernable by astrology. By choosing this test we were thus trying to maximize the ability of the astrologers to match CPI data with natal charts without introducing a pro-astrology bias. Other experiments have been done using the CPI with apparently positive results⁴.

The CPI consists of 480 true-false questions, each of which helps to rank a subject on one of 18 personality attribute scales (for example, dominance, passivity, femininity, masculinity). The subject's score on each scale is compared to the norm for that scale. The scores can be plotted on a graph (see Fig. 2) which readily conveys this information. Such a graph is called a 'CPI profile'.

Personality tests were graded, after names had been replaced by code numbers, by volunteers (undergraduate students) who were in no other way connected with the experiment. From spot

checks of the grading, we determined (95 per cent confidence level) that mistakes by the graders contribute an error of more than two points to CPI scores on fewer than 2.6 per cent of the individual scores, an insignificant effect.

Subjects were solicited by advertisements in San Francisco Bay area newspapers, classroom announcements and postings on and off the Berkeley campus. (To protect the confidentiality of the data and the rights of subjects, all procedures were checked by the University of California Office of Fair Treatment to Human Subjects before beginning data collection.) Approximately 70 per cent of the subjects were college students and about one half of these were graduates. All subjects were required to fill out a questionnaire with their natal data (birthday, including exact time and location of birth). They were also asked whether they (1) believe in astrology, (2) believe somewhat, (3) have no opinion, (4) disbelieve or (5) strongly disbelieve in astrology, and to state whether they had ever had a natal chart constructed before. Subjects were not told that these questions affected subject selection, but those who chose "(5) strongly disbelieve" were eliminated, on the grounds that this opinion might bias them, either consciously or unconsciously, against selecting the interpretation which best fitted them. All those who had previously had a chart constructed were similarly eliminated because they might be able to select (or reject) the correct interpretation based on a knowledge of what to expect. Strong believers who had never had their charts done were, however, not eliminated; this belief alone could not help them select the correct interpretation. All subjects had to be at least 17 years old. Failure to take the CPI resulted in rejection.

To avoid the possibility that a subject may have had his natal chart constructed elsewhere, or may have changed his opinion about astrology, between the time he submitted his natal data and the time he was given the final natal interpretations (typically 8–10 weeks), all subjects were required to fill out a new questionnaire before being asked to choose their own natal interpretations in Part 1 of the experiment. Two subjects were eliminated at this point, one who admitted to being a professional astrologer (and who had apparently lied on the first questionnaire) and another whose opinion of astrology had changed from "disbelieve in astrology" to "strongly disbelieve in astrology".

We encouraged prospective subjects to participate by promising them a copy of their natal chart, CPI test results and interpretation, the completed natal interpretation, and a copy of the final results of the experiment.

Although we required a departure from random of only 2.5 standard deviations to interpret the results as favouring the astro-

Fig. 3 Histogram showing weights assigned by astrologers to the CPI profiles they felt best fit the natal charts. CPI profiles rated higher are not more likely to be correct.

logical thesis, we originally planned to be able to distinguish between the two hypotheses at the four standard deviation level. This is why the number of subjects required was chosen to be 128, with a further 128 as a control group. Thus the total number of subjects was originally 256, but many of these did not complete all phases of the experiment.

Many lost interest and did not return their data to us. Some moved in the time taken to send them the test materials and did not leave a forwarding address. Two room-mates became emphatically convinced that astrology was the work of the devil, and refused to continue in what they called 'an experimental test of evil'. We were forced also to eliminate 12 subjects either because they did not follow directions correctly or did not return all the needed materials to us.

The use of double blind techniques is most important during this stage of the experiment. During the process of rejection of data, the experimenter had no access to any information that might introduce bias. In the end, only 177 subjects (83 test group, 94 control) remained for Part 1 of the experiment. Neither were we able to collect all the data we had hoped to in Part 2 of the experiment. First, fewer astrologers than hoped for agreed to participate. 224 data envelopes were mailed to only 28 astrologers, some of whom simply refused to participate as promised. Some declined after they discovered how much time was required on their part. One tried to bargain his services in exchange for free access to our raw data, and declined to participate when his terms were refused. For these reasons, we obtained only 116 usable subjects for Part 2 of the experiment. The large reduction in numbers was unanticipated and reduced the expected discrimination between hypotheses for Part 1 to 3.2 stan-

dard deviations, and for Part 2 to 3.9 standard deviations. However we do not believe that the loss of data could bias the results of the experiment in any significant way.

Bias and control

Experiments using human subjects are subject to a special class of biases which do not normally have to be considered by a physical scientist. An experiment must be designed so that the psychology of the subjects will not alter the results. The major potential biases which required specific control in the experiment design were as follows:

Sun-sign bias. By the astrological definition, the 'Sun-sign' refers to the constellation of the zodiac in which the Sun resides when the person is born. If the Sun-sign should play an important role in the average chart and if people are generally familiar with the characteristics of their Sun-sign (through newspaper horoscopes, for example), we might expect them to select the correct interpretation at a better-than-chance level regardless of whether or not the astrological hypothesis is correct.

To correct for this, each member of the test group was matched to a member of the control group born under the same Sun-sign. Following the astrologers' recommendations, we required that the age difference between these subjects be at least three years, so that their natal charts would be 'sufficiently dissimilar', but otherwise, the assignment was made randomly. Both test and control subjects were given the same three interpretations.

If the astrological hypothesis is false, members of both groups should identify the test subject's interpretation with equal frequency. If the hypothesis is true, the test group should score significantly higher than the control.

We believe that many other sources of bias are eliminated by the design of the experiments and by the standard formats in which data was conveyed to and from the astrologers. The possibility that subjects (in Part 1) would be tempted to choose flattering interpretations (or the opposite) should not bias our conclusions, given that we are comparing hits and misses between test and control groups. We sought to eliminate from the interpretations clues to their origin that might guide a subject to a correct choice, such as astrological terms that might be part of subjects' general knowledge, and to eliminate from the data with which astrologers worked, information that might allow them, consciously or otherwise, to bury hidden clues in their interpretations. Thus we eliminated from the charts transmitted to the astrologers information about the time and place at which subjects had been born. (Although the charts in principle allow the reconstruction of this information, the process is time-consuming, and the outcomes unlikely to be of direct help to

astrologers.) We did not tell the astrologers of the gender of the subjects, partly because gender-specific elements of the interpretations might lead to bias, but also because the CPI scores cover different ranges for males and females.

To eliminate the possibility that subjects could pick up clues other than the astrological information we were testing, and to insure that the information given to subjects was as uniform, and thus as comparable as possible, the interpretations followed a predetermined format designed to specify what factors astrologers should derive from the chart and to set a limit on the length of written material. The format was developed in collaboration with the advising astrologers. The specific categories which astrologers were required to address were: (1) Personality/temperament; (2) relationships; (3) education; (4) career/goals; and (5) current situation. The astrologers typed each interpretation on pages supplied by the experimenter and containing the proper headings, again to keep the interpretations as uniform as possible.

The format also specifies: (1) that advice or predictions were not to be given, on the grounds that such information could not help the subject to select the correct interpretation but that it might well lead him to discard an accurate description because he disagrees with the advice or predictions given. (2) That no direct reference to the chart was to be made (e.g. "you have sun in Leo"). (3) That no information relating to the subjects' ages was to be given.

Subjects were asked to rate each section of each natal interpretation on a 1-10 scale. Then they were asked to write down, for each section, the code number of the interpretation which fitted them best and second best.

One complication of our study arises because a subject's ability to select the correct description of himself from a given group must depend on how well he knows himself. If people generally have an inaccurate self-image, one would not expect subjects to select the correct interpretation no matter how accurate are the results of astrology. We devised the following scheme to understand this potential bias.

The CPI is generally accepted by psychologists as a moderately accurate description of a person's personality. Each test subject was given his own CPI profile and two others randomly selected from the group. He was then asked to select the profile which he felt best fitted him. Each subject was provided with the following: (1) three sample CPI profiles; (2) a synopsis of what high and low scores in each category tend to be for males and females; (3) a letter explaining about a CPI profile and how to go about making the selection.

To control for possible psychological bias, we elected to use the same test and control groups as in Part 1, but since the CPI is graded on different scales for males and females, we had to match male

Scientists wishing to familiarize themselves with astrology as astrologers practise it may find the following works useful:

(female) test group members to male (female) control members. Thus, the test-control group assignments had to be re-established.

Obviously, since the natal chart depends entirely on the natal data, inaccuracies in the latter would produce inaccuracies in the former. The astrologers insisted that the birth time be accurate to within 15 minutes. In order to assure this, when the subjects took the CPI, they were obliged to show documentation of their natal data including, especially, birth time. Although we preferred birth certificates, hospital and county record or other 'official' documentation, we also accepted baby books provided that the birth time was recorded when the child was born. (A more complete discussion of biases may be found in L.B.L. Preprint No. 20480.)

Double-blind procedures

An important difference between this and many previous tests is our extensive use of double-blind techniques. The important procedures we followed are outlined below.

As soon as subjects had taken the CPI, their questionnaires were put into alphabetical order and given to an assistant, who assigned a five random-digit code number to each in turn. No two subjects were assigned the same code number. The assistant then filled out three 3 × 5 index cards for each subject. On the first he put

Name-Code Number; these he filed in alphabetical order. On the second he put Code Number-Name; these were filed in numerical order. The purpose for these cards was for easy record-keeping. The cards were maintained under the supervision of Prof. Muller, and could be released to the experimenter only with his consent. At no time during the data collection did the experimenter have access to any information relating subjects' identities to code numbers. This control was abandoned only when all the data had been collected and the methods of analysis had been established.

The assistant also made a third set of cards each containing the code number of a particular subject and his natal data. These cards were given to astrologers Michael Caveney and Chris Nelson in envelopes unopened by the experimenter, for the construction of natal charts. Since the CPI was given at three different sessions (typically about 4 weeks apart), not all the assignments were made at the same time, nor did the astrologers receive all the natal data cards at one time. They did receive, however, the natal data cards within five days of the CPI testing dates.

Subjects who failed to show documentation of birth time, date and location when they took the CPI were automatically put into the control group (there were 43 such subjects). All questionnaires in each group were sorted into twelve Sun-sign groups. We then randomly assigned subjects to the control group until the number of control group members equalled the number of subjects remaining in each Sun-sign group. The remaining subjects comprised the test group. If there was an odd number of subjects in a Sun-sign group, the odd person was put in the control group.

The questionnaires in each Sun-sign group were then shuffled thoroughly and the names and birthdates were listed in the order in which they landed. As stated earlier, we required the birth dates to be at least three years apart to ensure that the natal charts were sufficiently dissimilar. The first test subject of each Sun-sign group was then matched to the first control subject of the same group whose birth date was far enough apart. The procedure was repeated for the second, third, etc. test subjects until we were left with test and control subjects whose birthdates were within three years of each other (which happened in all 12 Sun-sign groups).

To include these remaining subjects, we were forced to do some rematching in the

Table 1 Data from subject selections of natal chart interpretations

	Total	First choice	Second choice	Third choice		
Test group	56	25	16	15	18.67 ± 3.53	CPI PROFILE
Control group	50	21	13	16	16.67 ± 3.33	SELECTION
Test group	83	28	33	22	27.67 ± 4.29	INTERPRETATION
Control group	94	42	34	18	31.33 ± 4.57	SELECTION

following way. We started at the top of the control group and went down until we found a birthdate which satisfied the requirements that it was at least three years away from the unmatched test person and that the birthdate test group member to which it was attached was at least 3 years away from one of the unmatched controls. We then rematched the originally-matched control group member with the previously unmatched test subject, and matched the unmatched control group member with the previously matched test member. This was continued until all the test and control group subjects were matched. Because seven Sun-sign groups had an odd number of subjects, there remained seven unmatched control group members.

For the second part of the experiment, male (female) test members had to be assigned to male (female) control members. Thus, the above test subject to control subject matching had to be redone. Since the test and control groups were randomly chosen, no changes in them were made. However, all the matchings changed as male (female) test subjects were randomly matched to male (female) control subjects.

During the conduct of the experiment, each subject was given two envelopes, one containing the materials needed for the selection of the natal chart interpretation and the other containing the materials for the selection of the CPI profile. The natal interpretation envelope contained: (1) three natal interpretations; (2) a pretyped sheet on which the subjects were to detail their choices; (3) a questionnaire asking their opinion of astrology and whether they had had their chart done before (See Experiment Design); and (4) a letter explaining how they were to go about making the selections. The CPI envelope contained: (1) three CPI profiles; (2) a preformatted sheet on which the subjects were to detail their first and second place choices, plus 1-10 ratings; (3) a summary of what the CPI scores mean; and (4) a letter explaining how they were to go about making their selections. Since we had labelled the natal charts with the code number of the person for whom they were constructed, we could not do the same with the CPIs, since the subjects might recognize a code number appearing twice. The CPIs were first labelled with the code numbers of the persons to which they corresponded, and then relabelled by finding

Fig. 4 Graph showing percentage correct versus rating for astrologers first place choices in CPI profile natal chart matching. The best linear fit is consistent with the scientifically predicted line of zero slope. No significant tendency for the astrologers to be more correct when they rate a CPI as highly matching a natal chart.

$\ln(1/x)$ for each code number, x , on a hand calculator and taking the last 5 digits on the calculator display as the new code number. All natal interpretations and CPI profiles were put in numerical order in the envelopes.

The astrologers were sent materials in two separate mailings. In the first, each received: (1) the number of natal charts he had agreed to interpret when he chose to take part (typically 4); (2) a copy of the format by which the charts were to be interpreted; (3) the paper with headings on which the interpretations were to be typed; (4) a letter explaining the symbols used on the computer-constructed natal charts, deadlines and notice of when they might expect the materials for part two of the experiment; (5) a postage-paid return envelope. After they had returned the natal charts and interpretations, the astrologers received the second mailing containing: (1) the number of natal charts (plus three CPIs for each natal chart) which they had agreed to match to CPI profiles; (2) a copy of *The Interpreter's Syllabus for the CPI*² (a booklet explaining all the CPI attributes and how to interpret them in detail); (3) a preformatted sheet on which the astrologers were to detail their first and second choices and ratings; (4) a letter explaining how to go about making the choices; (5) a postage-paid return envelope for the data.

To save the astrologers work, they were allowed to make the CPI matchings to the natal charts they had already interpreted. They were also typically sent an additional natal chart and CPIs to match. To ensure that the astrologers would not mix up the CPI profiles between natal charts, the three profiles for each natal chart were ordered randomly, then labelled *a*, *b* and *c* respectively.

A total of 226 natal charts were sent out to be matched with CPI profiles. Of these, only 15 had no documentation of birth time. None of these 15 were returned by the astrologers to be included in our data.

Results

Part 1. Subject selection of natal chart interpretations. After a predetermined data collection period of 10 weeks, we had astrological data from 83 test and 94 control subjects and CPI self-selection data from 56 test and 50 control subjects. The data are displayed in Table 1.

The test group selected the correct interpretation as its first choice at the rate of 0.337 ± 0.052 , the control group at the 0.447 ± 0.049 rate, 2.34 standard deviations above chance. Although this fluctuation is less than 2.5 standard deviations, the level we had chosen to call 'significant', it does require comment. Since this fluctuation occurred in the control group and control subjects were not given their own interpretations, this cannot be interpreted as a possible astrological effect. Neither can it be correctly attributed to Sun/sign bias, since the test group did not score near the same level. We thus interpret this as a statistical fluctuation. The test group chose the correct interpretation as second best, describing them at the 0.398 ± 0.052 rate while the control group did so at the 0.362 ± 0.049 rate. Finally, the correct interpretation fell as the test group subjects third choice at the 0.265 ± 0.052 level and, for the control group, at the $0.191 \pm$

Table 2 Data from astrologers matching natal charts to CPI profiles

	Total (n)	Chance (n/3) [Expected s.d.]	Astrologers predicted (n/2) [Expected s.d.]	No. of correct CPI chosen	Standard deviation away from 0.35	Standard deviation away from 0.50
First choice	116	38.5 [5.1]	58.5 5.4	40	+2.56	3.34
Second choice	114	38.0 [5.0]	None	46	+1.48	—
Third choice	114	38.0 [5.0]	None	28	2.0	—

The data are consistent with chance, inconsistent with astrological hypothesis.

0.049 rate. All this is consistent with the scientific hypothesis.

When the first few data envelopes were opened, we noticed that on any interpretation selected as a subject's first choice, nearly all the subsections were also rated as first choice. We then realized that we had no way of guaranteeing that subjects were rating each section of the interpretations independently of others they had already read. Without such a guarantee, spurious results favouring either hypothesis could have easily appeared. So we rejected these data as not having been collected under the proper controls.

Next we looked to see how well the subjects were able to select the correct CPIs. The test group selected the correct CPI as their first choice at the 0.446 ± 0.063 rate, while the control did so at the 0.420 ± 0.066 rate, showing no significant difference between the two groups. The test group chose the correct CPI as the second place choice at the 0.286 ± 0.063 rate, while the control did so at the 0.260 ± 0.066 rate, again no significant difference between the two groups. Finally, the test group chose the right interpretation as their third choice at the 0.268 ± 0.063 rate while the control group did so at the 0.320 ± 0.066 rate. Once more, there is no significant difference between the two groups.

Part 2. Natal Chart-CPI matching. A total of 116 data envelopes were returned by the astrologers. In the 116 envelopes there was a total of 116 first place choices, 114 second place choices and 320 ranked choices (weight factors indicating how well the astrologers felt the natal chart matched each CPI, on a scale of 1 to 10) (Table 2).

The data were first analysed without taking the 1-10 weight factors into account. The astrologers selected the correct natal chart as their first place choice at the 0.34 ± 0.044 rate, in agreement with the scientific hypothesis of 0.33 and in disagreement with the astrological hypothesis of 0.5 by 3.3 standard deviations. The correct CPI was chosen as the second place choice at the 0.40 ± 0.044 rate which is also consistent with the scientific hypothesis. (The astrologers had made no firm prediction about the second place choice.) The correct CPI was chosen as the third place choice at the 0.25 ± 0.044 rate, again consistent with the scientific hypothesis.

Next we took the weights into account, by a method established before studying the data. (The establishment of methods before data analysis is important in order to prevent the subtle bias that comes from selection of analysis procedures.) We first made a histogram of the weights which the astrologers assigned to all their place choices, regardless of whether or not those choices were correct (Fig. 3). The data are sharply peaked at a weight of about 8. The second histogram in Fig. 3 shows the ratings of only those first place choices which

Fig. 5 Histograms showing rates assigned to astrologers' second (a) and third (b) place choices.

Fig. 6 Percentage of correct CPI profiles versus rates, chosen by astrologers as their second (a) and third (b) place choice. Best linear fits are consistent with chance.

were correct. If the astrological hypothesis were true, one might expect the correct first place choices to have higher weights on average than the whole group of first place choices. Thus, the new histogram should be skewed to the right. On comparing the two histograms, however, we see that they are very similar; no such skewing appears.

The scientific hypothesis predicts that 1/3 of the choices at any weight should be correct choices. Figure 4 shows the percentage correct for each weight with the appropriate error bars, and the best linear fit with slope -0.01 ± 0.02 . The slope is consistent with the scientific prediction of zero slope. The same analysis on the second and third place choices yields Figs 5a, b and 6a, b. The slope of the best linear

fit to the data on Fig. 6a is 0.019 ± 0.02 while that of Fig. 6b is 0.0026 ± 0.02 both consistent with the scientific hypothesis (zero slope).

Conclusions

From the results of Part 1 (subjects selecting interpretations), we notice that the test group scored at a level consistent with chance and within 2.5 standard deviations of the control group. The large (2.34 s.d.) but not significant (less than 2.5 s.d.) fluctuation in the control group is attributable to statistical fluctuation, not to a Sun-sign bias. These results are consistent with the scientific hypothesis. However we cannot use the result to rule against the astrological hypothesis, because the test subjects were also unable to select their

own CPI profile at a better-than-chance level. At the 95 per cent confidence level, the test subjects were unable to select their own CPI profile at better than the 0.57 rate. There are many reasons which could explain why the test subjects were unable to select the correct CPIs at a higher rate:

- (1) Subjects may have had difficulty relating to the graphical presentation of the CPI information.
- (2) Some subjects may have recognized correct information about themselves, but subconsciously chose a CPI which did not describe them as well to avoid admitting they have certain character traits. Such denial in a large percentage of the subjects would tend to cancel a positive effect.
- (3) The CPI may not test the kind of attributes by which subjects may easily recognize themselves.
- (4) People may be unable to recognize accurate descriptions of themselves.

Our experiment does not distinguish between these possibilities. Professor H. Gough (author of the test and respected experimental psychologist) is familiar with nearly all published experiments using the CPI. At our request he searched through the literature for any experiment demonstrating the ability of test subjects to recognize accurate descriptions of themselves. To his and our knowledge, no other test of this kind has ever been done. Thus, we believe there exists presently no scientific evidence from which one can conclude that subjects can select accurate descriptions of themselves at a significant rate.

If subjects cannot recognize accurate descriptions of themselves at a significant level then the experiment would show a null result no matter how well astrology worked. On the other hand, any astrological effect demonstrated in this way would require a consistency check. One would have to see if subjects could recognize the kind of information astrologers give them about themselves, which was derived in a manner *known* to be reliable. Thus, until and unless such a self-recognition ability can be shown, we conclude that subject selection of astrologically derived information is a poor test of astrology. (This is a problem in approximately 30 per cent

of all experiments which claim a significant astrological effect.)

The conclusions to be reached from Part 2 (CPI-natal chart matching) of the experiment are somewhat more illuminating. What is striking about these data is how poorly the astrologers performed, when their performance is compared to their predicted rate. It is consistent with chance, and is at the very significant 3.3 s.d. level below the astrologers' prediction. This is well beyond the 2.5 s.d. requirement we established before the beginning of the experiment as sufficient to refute the astrological hypothesis.

Before the data had been analysed, we had decided to test to see if the astrologers could select the correct CPI profile as either their first or second choice at a higher than expected rate. The scientific hypothesis predicts the CPI will fall in the first or second choice 66 per cent of the time. The astrologers did not make a specific prediction as to what they expected the rate to be. If the correct CPIs are chosen in the first and second place choices, then they will be depleted from the third place choice. Since the rate at which the astrologers chose the correct CPI as their third place choice was consistent with chance, we conclude that the astrologers were unable to choose the correct CPI as their first or second choices at a significant level.

In Fig. 4 the data are clearly inconsistent with the 'at least' 0.5 level predicted by the astrologers. Nor do the data suggest that the astrologers are more likely to be correct when they rate a CPI as well fitting the particular natal chart than they are when they weight it as poorly fitting the natal chart. The data appear randomly scattered about the 0.33 line and is hence consistent with chance. The scientific hypothesis predicts a line of zero slope, consistent with the slope observed. Figures 5 and 6 likewise show no convincing evidence that the astrologers tended to rate the correct CPIs higher than the incorrect CPIs.

We are now in a position to argue a surprisingly strong case against natal astrology as practised by reputable astrologers. Great pains were taken to insure that the experiment was unbiased and to make sure that astrology was given

every reasonable chance to succeed. It failed. Despite the fact that we worked with some of the best astrologers in the country, recommended by the advising astrologers for their expertise in astrology and in their ability to use the CPI, despite the fact that every reasonable suggestion made by the advising astrologers was worked into the experiment, despite the fact that the astrologers approved the design and predicted 50 percent as the 'minimum' effect they would expect to see, astrology failed to perform at a level better than chance. Tested using double-blind methods, the astrologers' predictions proved to be wrong. Their predicted connection between the positions of the planets and other astronomical objects at the time of birth and the personalities of test subjects did not exist. The experiment clearly refutes the astrological hypothesis.

I thank Professor Richard Muller for providing funding from his Alan T. Waterman Award, and for invaluable assistance and guidance; Professor Doksum, Statistics, UC Berkeley, for acting as an advisor at the conception of the experiment; Tony Joseph for many helpful conversations and for being our astrological advisor; Michael Caveney and Chris Nelson for constructing the natal charts and being astrological advisors; the participating astrologers for their expertise, time, and effort; Terry Mast, Teresa Weed, Geoffrey Dean for helpful criticisms; Kent McArthur who first suggested the use of personality tests; Susan Miller, who assisted in the advertising, and to those Berkeley undergraduates who gave up their time to act as assistants and CPI test graders.

Direct observation of He^+ pick-up ions of interstellar origin in the solar wind

E. Möbius*, D. Hovestadt*, B. Klecker*, M. Scholer*, G. Gloeckler† & F. M. Ipavich†

† Department of Physics and Astronomy, University of Maryland, College Park, Maryland 20742, USA

Singly-ionized helium with a velocity distribution extending up to double the solar wind velocity has been detected in interplanetary space. This distribution unambiguously determines the source: interstellar neutrals, ionized and accelerated in the solar wind. The observed significant flux increase in early December is due to the gravitational focusing of the interstellar neutral wind on the downwind side of the Sun.

THE penetration of the interstellar medium into the heliosphere and the interaction between the solar wind and the interstellar gas have been of great interest for many years¹⁻⁴. The first experimental evidence of neutral interstellar hydrogen penetrating into the heliosphere was obtained from Lyman α sky background mapping^{5,6}. Similar observations of interstellar helium using the He I 584-Å resonance line⁷⁻⁹ revealed the existence of an interstellar neutral wind in interplanetary space which is subjected to the forces of solar gravitation and radiation pressure. When approaching the Sun, the interstellar gas is ionized by solar ultraviolet radiation, by charge exchange with solar wind ions and by collisions with solar wind electrons. The newly created ions are then picked up by the solar wind through interaction with the interplanetary magnetic field.

While most of the constituents are already ionized far beyond the orbit of the Earth, neutral helium (because of its high ionization potential) approaches the Sun to <1 AU (ref. 1). Therefore, a significant fraction of the helium is ionized inside the Earth's orbit and one would expect that these ions are observable by spacecraft in the solar wind. So far, no conclusive measurement on He^+ ions of interstellar origin has been given. Although signatures of He^+ in the solar wind with varying abundances have been reported occasionally^{10,11}, a systematic search for a permanently present flux of interstellar He^+ as part of the solar wind resulted only in upper limits more than one order of magnitude below the estimated flux levels¹². After this negative result Vasyliunas and Siscoe¹³ suggested that the newly created He^+ ions may not be thermalized rapidly enough to occur within the solar wind distribution. The expected broad energy and angular distribution of the interstellar helium ions, however, was not visible to the particle detectors flown on spacecraft up to now. A search for interplanetary He II emission at 304 Å was also not conclusive¹⁴. In this article, we will report measurements with a time-of-flight (TOF) spectrometer in which the interstellar helium ions and their velocity distribution in the solar wind are clearly identified for the first time.

Instrumentation and spacecraft

The data presented here were obtained with the SULEICA (Supra-thermal Energy Ionic Charge Analyser) instrument of the Max-Planck-Institut and the University of Maryland onboard the IRM spacecraft of the AMPTE (Active Magnetospheric Particle Tracer Explorer) project. The IRM was launched on 16 August 1984, into a highly elliptical orbit with an apogee of $18.6 R_E$. During the time period from launch until December 1984 the satellite spent a large fraction of each orbit in the solar wind upstream of the Earth's bow shock.

The SULEICA instrument combines the selection of incoming ions according to their energy per charge by electrostatic deflection with a subsequent TOF analysis and the final measurement of the residual ion energy in a silicon surface barrier detector. The energy range from 5 to 270 keV/charge is covered by stepping the analyser voltage in 24 logarithmically spaced voltage steps in synchronism with the spacecraft spin. The fan-like

Fig. 1 Typical TOF-histograms at three different energy steps taken in the Sun sector and the two adjacent sectors. The data were obtained during a period of 45 min on 11 November 1984, at $\sim 18 R_E$ in front of the Earth's bow shock.

aperture of the electrostatic analyser (two concentric segments of a sphere) covers a solid angle of 10° in azimuth and 40° in elevation symmetric to the plane perpendicular to the spacecraft spin axis. The directional information in azimuth is provided by a sectoring scheme with 16 sectors for protons and α particles and eight sectors for the other ions. The geometrical factor of the instrument is $4.3 \times 10^{-2} \text{ cm}^2 \text{ sr}$ and its energy resolution is $\Delta E/E \approx 0.097$. A more detailed description may be found elsewhere¹⁵.

The expected energy of the pick-up ions (≤ 40 keV) is too low to create energy signals significantly above the noise level of the solid state detectors. Therefore, the ion species are identified by combining the electrostatic deflection (E/Q) and the TOF signal. For each specific E/Q step, the TOF distribution represents a unique mass-per-charge distribution, since $M/Q \sim E/Q \times \text{TOF}^2$. Recently this type of analysis has been successfully applied to identify Li^+ pick-up ions after the lithium vapour cloud releases of the AMPTE project in the solar wind¹⁶.

Basic observations

For the present investigation a limited number (12) of observational periods in the solar wind were chosen between launch of the spacecraft and the end of December 1984. During all periods we observe a significant peak at $M/Q = 4$ in the TOF-histograms for E/Q steps which correspond to energies higher than we would expect for genuine singly charged solar wind helium. Depending on the E/Q step we also observe a broad and variable peak at TOF-values which correspond to the actual

Fig. 2 Differential energy flux spectrum of the $M/Q=4$ channel taken in the Sun sector with an accumulation time of 40 min. The dashed line represents the 1 count level for each energy.

solar wind velocity. These ions with M/Q values well above 4 represent heavy ions of the solar wind. In addition, the signature of the He^+ ions at $M/Q=4$ is also seen in the two sectors adjacent to the sunward direction. A typical example of TOF-histograms for three different voltage steps and all three azimuthal sectors with the He^+ peak is shown in Fig. 1. The sample was taken during a 45-min interval on 11 November 1984, when no energetic ions occurred upstream of the bow shock. Note, however, that the He^+ signature is visible at all orientations of the interplanetary magnetic field and is independent of whether or not upstream particles are present.

Figure 2 shows the differential energy flux spectrum of the He^+ ions in the Sun sector for the same time period. The spectrum is basically flat between ≈ 8 and 22 keV with a sharp cutoff at ≈ 22.3 keV. This value corresponds to about four times the solar wind bulk energy of helium (indicated by the vertical line) for this time period. The actual solar wind velocity was 550 km s^{-1} , as derived from the data of the Max-Planck-Institut/University of California Berkeley three-dimensional-Plasma instrument on IRM¹⁷. Below 8 keV a sharp rise of the spectrum occurs which is attributed to solar wind ions with $M/Q=4$, for example, Si^{7+} and S^{8+} (ref. 12). The dashed line in Fig. 2 indicates the one count limit for He^+ .

Signature of pick-up ions

In contrast to genuine solar wind ions heavier than protons, which flow with almost solar wind bulk velocity, freshly created ions in interplanetary space are initially at rest. After ionization they are immediately subjected to the combined forces of the interplanetary $v_{\text{sw}} \times B$ electric field and the magnetic field B where v_{sw} is the solar wind velocity. In the inertial system (which coincides with the rest frame of the spacecraft), the ions initially perform a cycloidal motion perpendicular to the local magnetic field. The velocity varies between basically zero (the velocity of the neutral wind at $\approx 20 \text{ km s}^{-1}$ is neglected compared with the solar wind velocity) and a maximum value

$$v_{\perp \text{max}} = 2 v_{\text{sw}} \sin \alpha \quad (1)$$

which is determined by the solar wind velocity and the angle α between its flow direction and the local magnetic field. The maximum energy of pick-up ions then is

$$E_{\perp \text{max}} = 4(M/2)v_{\text{sw}}^2 \sin^2 \alpha \quad (2)$$

In the solar wind frame, the pitch angle distribution of these particles is a ring in velocity space with the pitch angle α , that is, the ions gyrate with $v_{\perp} = v_{\text{sw}} \sin \alpha$ and move along the magnetic field with $v_{\parallel} = v_{\text{sw}} \cos \alpha$. Observations of artificially-injected lithium in the solar wind which have been made within the first cycloid after the ionization are compatible with such

Fig. 3 a, Cut through the fully developed velocity distribution of pick-up ions in the spin plane of the spacecraft (shaded area) along with the sectoring and voltage stepping scheme of the instrument. The velocity space element, which is used to determine the differential energy flux as seen by the instrument, is left blank. b, Similar representation in the solar wind frame. The velocity space element, over which the actual integration is performed, is left blank.

an undisturbed pick-up distribution¹⁶. Our observations of He^+ ions, which are spread over a large volume in velocity space, seem to indicate a significant broadening of the initial ring distribution in pitch angle as well as in energy.

Cosmic rays are strongly pitch-angle-scattered by magnetic field fluctuations in the solar wind, while their energy remains almost unaffected¹⁸. The corresponding mean free path for scattering of He^+ pick-up ions (with a typical magnetic rigidity of 5–10 MV) turns out to be about 0.05 AU according to a compilation of cosmic-ray propagation parameters¹⁹. From these arguments, pitch angle scattering seems to be rather efficient for pick-up ions, and shortly after ionization a spherical shell distribution in velocity space is formed within the rest frame of the solar wind. Initially, the ions are injected into the solar wind with the energy $E_0 = (M/2)v_{\text{sw}}^2$ (with velocity components v_{\parallel} and v_{\perp} as discussed above). Therefore, the radius of the spherical shell distribution is equal to the solar wind velocity. Subsequently, the ion energy decreases as a result of adiabatic deceleration during the radial transport with the expanding solar wind. Due to adiabatic deceleration the energy of fully pitch-angle-scattered particles varies like

$$E/E_0 = \left(\frac{r_i}{r}\right)^{4/3} \quad (3)$$

with the distance r from the Sun, starting at the location of birth of the ion r_i (ref. 13). This relation immediately leads to a mapping of the spatial source distribution of pick-up ions upstream of the spacecraft into an energy or velocity distribution in the solar wind frame at the location of the satellite which can be written as:

$$f(v) = \frac{3N_0 v_{\text{ion}} r_0}{8\pi v_{\text{sw}}^4} \left(\frac{v}{v_{\text{sw}}}\right)^{-3/2} \quad (4)$$

N_0 and v_{ion} are the neutral density and the ionization rate of the interstellar gas at the Earth's orbit ($r_0 = 1 \text{ AU}$). v_{ion} is assumed to vary like $1/r^2$ with the intensity of solar ultraviolet radiation. In the spacecraft frame of reference, this results in a particle distribution which extends between $E=0$ and a maximum energy

$$E_{\text{max}} = 4E_{\text{sw}} = 4(M/2)v_{\text{sw}}^2 \quad (5)$$

for particles coming from the sunward direction. Such a distribution with a more or less flat spectrum in differential energy flux is, indeed, observed between about 8 and 22 keV (see Fig. 2).

From these observations, it can be concluded that the velocity distribution of the pick-up ions is basically a full sphere centred at the solar wind velocity. A cut through this distribution in the plane perpendicular to the spin axis of the satellite is shown in Fig. 3. The azimuthal sectoring scheme and the voltage stepping

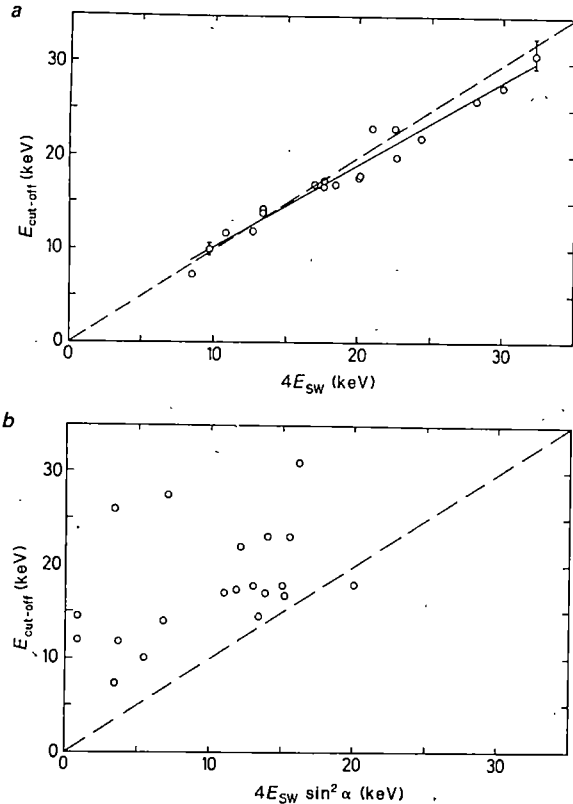

Fig. 4 Correlation of the experimental cutoff energies of the He^+ spectrum with the fourfold solar wind bulk energy $4E_{\text{SW}}$ of helium (a) and with the maximum pick-up energy perpendicular to the interplanetary magnetic field $4E_{\text{SW}} \sin^2 \alpha$ (b).

scheme (concentric circles) are overlaid. This interpretation is also supported by the TOF histograms shown in Fig. 1, where the He^+ peak is observed in the Sun sector 4 as well as in the neighbouring sectors 3 and 5. The energy spectrum displayed in Fig. 2 represents a cut through the distribution in the Sun sector. It follows from the measured flat energy spectrum that a large fraction of the sphere in velocity space rather than only the outer shell is filled with He^+ ions. Otherwise, a significant flux decrease between E_{SW} and $4E_{\text{SW}}$ would be expected. Therefore, a significant part of the He^+ population originates from locations several tenths of an AU upstream of the spacecraft. The energy of these ions has decreased on their way according to relation (3).

The energy spectra of the He^+ ions have been investigated for several time periods of different solar wind velocities and interplanetary magnetic field directions. In Fig. 4, the observed cutoff energies E_{cutoff} (defined by a decrease of the differential energy flux by a factor of 10 compared with the mean plateau level) are plotted first against the fourfold solar wind bulk energy $4E_{\text{SW}}$ of helium as given by relation (5) and second against the initial maximum pick-up energy $4E_{\text{SW}} \sin^2 \alpha$ according to relation (2). There is an excellent correlation with the full four-fold solar wind energy (correlation coefficient 0.98), while the correlation with the maximum pick-up energy is very poor (correlation coefficient 0.36). This result clearly indicates that the pick-up ions in all conditions have mainly lost their directional information due to pitch angle scattering and that most of the ions originate from regions beyond one mean free scattering length (0.05 AU) upstream of the observer.

Note that the generation of several types of plasma waves by the highly unstable distribution of pick-up ions has been discussed in the past^{20,21}. These waves were expected to lead to a complete thermalization in energy of the pick-up ion distribution in the solar wind frame of reference in addition to pitch angle scattering. However, the results described above—in particular, the sharp cutoff in energy—indicate that the influence of these waves on the He^+ distribution can be neglected compared with the adiabatic cooling.

Fig. 5 Differential energy flux of 20-keV He^+ ions obtained in the Sun sector for five different time periods between September and December 1984.

Source of the He^+ ions

Knowing the velocity distribution of the He^+ ions as shown in Fig. 3, the source strength $S = N_0 v_{\text{ion}}$ of the pick-up ions can be obtained from the measured differential energy flux at a fixed energy. The differential energy flux can be calculated by integrating the distribution function (relation (4)) over one voltage step and the Sun sector in the spacecraft frame (blank area in Fig. 3a). Instead of performing the full transformation from the solar wind frame into the spacecraft frame we use the fact that the distribution is isotropic in the solar wind frame and that near the maximum energy of the ion distribution (in the Sun sector) the volume element in velocity space $\Delta \Omega v^2 \Delta v$ covered by one energy channel of the instrument appears to be extended by a factor of four in solid angle in the solar wind frame compared with the spacecraft frame as indicated in Fig. 3b. Within this approximation, the integration is performed over the corresponding sector in the solar wind frame (blank area in Fig. 3b). Using the distribution function (5) we obtain for the differential energy flux:

$$\frac{\Delta J E}{\Delta E} = \frac{3 N_0 v_{\text{ion}} r_0 E}{8 \pi \Delta \Omega \Delta E} 4 \Delta \Omega \frac{1}{v_{\text{sw}}^4} \int_{0.9 v_{\text{sw}}}^{v_{\text{sw}}} \left(\frac{v}{v_{\text{sw}}} \right)^{-3/2} v^3 dv \quad (6)$$

According to the energy resolution of the instrument ($\Delta E/E \approx 0.1$, corresponding to $\Delta v/v \approx 0.05$) the integration limits in velocity are $0.9 v_{\text{sw}}$ and v_{sw} in the solar wind frame. Note that the differential energy flux (compared with the differential particle flux $\Delta J/\Delta E$), when taken at the maximum energy of the pick-up distribution, does not vary with the solar wind velocity. Therefore, this quantity is a suitable parameter for subsequent long-time studies of the He^+ source. Using $w = v/v_{\text{sw}}$ we find:

$$\frac{\Delta J E}{\Delta E} = \frac{3}{2\pi} N_0 v_{\text{ion}} r_0 \frac{E}{\Delta E} \int_{0.9}^1 w^{3/2} dw \approx 0.5 N_0 v_{\text{ion}} r_0 \quad (7)$$

Taking an ionization rate $v_{\text{ion}} = 1.25 \times 10^{-7} \text{ s}^{-1}$ at 1 AU (ref. 9) a value of $N_0 r_0 = 1.2 \times 10^{11} \text{ cm}^{-2}$ is derived from the mean differential energy flux between 16 and 20 keV ($7 \times 10^3 \text{ s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$) on 11 November 1984. The actual column density upstream of the spacecraft corresponds to about half the value of $N_0 r_0$.

Possible sources for singly charged ions which are injected into the solar wind with zero velocity are the interstellar neutral gas as discussed above and, in addition, planetary atmospheres and cometary comae. Of the latter ones the only source of interest for the observations reported here is the Earth's atmosphere. In contrast to the interstellar gas, which is present over a large scalelength in interplanetary space, the terrestrial sources of neutral helium are rather localized. Because the density of the exosphere typically varies like $1/R^2$ with distance from the Earth, the remaining scalelength of Earth's exosphere (the outer regime of the atmosphere) beyond the location of the spacecraft ($18 R_E$) is of the order of $20 R_E$. Therefore, a terrestrial origin can be ruled out for the observed He^+ ions for two reasons.

First, the observed velocity distribution can only be explained in terms of a source which extends far beyond the mean free

scattering length of ~ 0.05 AU upstream from the Earth, while the terrestrial exosphere has a scalelength of typically $20 R_E$.

Second, with a scalelength of $\sim 20 R_E$ the measured column density would lead to a helium density of $\sim 5 \text{ cm}^{-3}$ at a distance of $18 R_E$. This value exceeds densities known for exospheric helium by more than 3 orders of magnitude²².

Therefore, the observed He^+ ions are most likely of interstellar origin. The corresponding helium density in interplanetary space upstream of the spacecraft on 11 November was determined to be $N_0 \approx 8 \times 10^{-3} \text{ cm}^{-3}$.

The flux of He^+ ions and, therefore, the neutral density of helium shows a significant variation over the observation period from September to December 1984. In Fig. 5, the differential energy flux of He^+ at 20 keV is plotted against time. For this analysis, only those time periods were taken when the solar wind velocity exceeded 550 km s^{-1} ; that is, the maximum energy E_{cutoff} was $> 20 \text{ keV}$. The differential energy flux is low in September and October ($\sim 2 \times 10^3 \text{ s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$). An increase by about a factor of 10 is observed until early December, after which the flux falls off again towards the end of December. This result is in good agreement with models of the spatial distribution of neutral helium in interplanetary space and the observations of $\text{He I } 584\text{-}\text{\AA}$ radiation^{8,9}. During December, the Earth is on the downwind side of the interstellar neutral wind with respect to the Sun. Here the helium is supposedly focused by the gravitational forces of the Sun and, therefore, the local density is enhanced significantly. The observation of this effect constitutes additional evidence for the interstellar source of the He^+ ions.

These observations are of particular importance, since various parameters of the local interstellar medium can be derived from the annual variation of the flux of He^+ ions: (1) the location of the apex; (2) the value of the relative velocity between the sun and the local interstellar medium; (3) the temperature; and (4) the density of the interstellar helium.

The absolute value of the density near the Earth as given above is compatible with results reported from ultraviolet measurements^{8,9}. A quantitative analysis of the density outside the heliosphere and the determination of the parameters of the local interstellar medium as listed under items (1) to (4) above requires a detailed comparison of the experimental results with

theoretical models of the neutral helium distribution in the heliosphere. This is beyond the scope of the present paper and will be presented in future work.

Furthermore, these pick-up ions represent a source of ions with a velocity distribution clearly distinguishable from the solar wind. To study their subsequent acceleration at the Earth's bow shock and at interplanetary shocks will be of great interest. Finally, these ions are most likely the seed particles for the so-called anomalous component of cosmic rays for which an interstellar origin and subsequent acceleration in the interplanetary medium²⁴ or at the terminating shock of the heliosphere²⁵ has been proposed.

We thank the many individuals at the Max-Planck-Institut and the University of Maryland who contributed to the success of the SULEICA instrument and to the AMPTE/IRM satellite. We thank H. Lühr for magnetic field data, G. Paschmann for solar wind velocity data, and M. A. Lee for helpful discussions in the interpretation of the ion distribution.

Axial processes along a segment of the East Pacific Rise, 10° – 12° N

G. Thompson*, W. B. Bryan*, R. Ballard*, K. Hamuro† & W. G. Melson‡

* Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

† Japanese Consulate, 600 Atlantic Ave, Boston, Massachusetts, USA

‡ Smithsonian Institution, Washington DC 20550, USA

Axial segments of the East Pacific Rise are made up of individual volcanoes. Each volcano has a distinct magma composition and shows a systematic variation in the fractional crystallization with distance along the axis from the central chamber. Hydrothermal venting, lava morphology and tectonics also vary along the axis. Lavas erupted near transform faults, from the tips of propagating rifts in overlapping spreading centres, and from near-axis seamounts have different and variable compositions.

MID-OCEAN ridge spreading centres have recently been shown to consist of discrete segments separated by transform faults and conjugate spreading centres (also called overlapping spreading centres (OSC) or non-transform offsets^{1,2}). Typically, in each segment the axial depth shows a minimum or topographic high at some point between the two ends^{1–4}. Francheteau and Ballard⁴ have proposed that the topographic highs lie above the principal magma chambers feeding lavas to the axis and are thermal expressions of such chambers. Their model predicts that relative volumes of lava and morphology of lava flows

should change systematically along the axis away from the topographic high. Specifically, pillow lavas should increase relative to sheet flows, fracturing should increase and hydrothermal activity should decrease along-ridge away from the topographic high. To date, observations supporting this hypothesis have been made at several locations of different spreading rates, but have been limited to a few kilometres along the axis in the vicinity of the axial topographic high.

We report here on our recent observations over a 180-km length of East Pacific Rise (EPR) axis between 10° and 12° N,

made specifically to test the Francheteau–Ballard model. This location (see Fig. 1) was deliberately chosen because the region had been recently mapped using SEABEAM⁵ and the axial depth and segmentation of the ridge was known. Starting at a major transform fault, the Clipperton Fracture Zone, the neovolcanic zone or zero-age axial depth shows a progressive shallowing to a first topographic high about 10°55' N, deepens to a topographic low, thought to be a small OSC at 11°15' N (ref. 1), rises to a second topographic high at 11°30' N, then deepens to a large OSC at 11°45' N with a distinct basin separating the overlapping ridge segments (Fig. 1). Previously, a French submersible dive^{6–8} on the second topographic high at 11°30' N had indicated intense (black smoker) hydrothermal activity. Thus, all the ingredients were present to test how axial processes varied along the axis with respect to major features such as topographic highs, OSCs and transform faults, and how (or if) magmatic activity and composition varied with distance from the proposed central magma chamber(s).

Variation along axis

Near the Clipperton Fracture Zone at the southern end of the studied ridge segment, the axial graben is not well developed, abundant fissures and talus indicate dominance of tectonic activity, and pillow lavas are the major eruptive form (but are often badly cracked; see Fig. 2a). These observations indicate that eruptions are infrequent. No hydrothermal activity was observed. Halfway along the segment between the Clipperton Fracture Zone and the first topographic high, the axial graben becomes well defined, although fissures are abundant near the graben walls. Within the graben, glassy lobate flows and broken platy sheet-flow lavas (Fig. 2b) indicate relatively recent eruptions, although tectonic activity is still noticeable. Some non-active hydrothermal formations were observed, although these are rare (Fig. 2c). At the first topographic high at 10°55' N (see Fig. 1b), the axial graben is very well developed, undeformed sheet-flow lavas (Fig. 2d) dominate in the graben floor, and hydrothermal activity, including white and black 'smokers', is common (Fig. 2e). Fissuring and faulting near the graben edges are not as abundant as farther south in the segment. Constructive volcanism dominates the topography. Glassy reflective flows are not common in the photographs but sampling recovered very fresh, glassy fragments of sheet flows and lobate flows with a thin mantling of iron-rich hydrothermal precipitate that dulls the surfaces.

The topographic low between the two highs, although previously indicated¹ to be an OSC, does not appear to have typical OSC features. The axial graben appears to be continuous and fresh lava flows and hydrothermal activity are seen. We infer, based on the observations and the magma chemistry, that the axial portion from the northernmost topographic high at 11°30' N has propagated southwards and linked up with the southern axis. The second topographic high at 11°30' N (see Fig. 1b) also shows a well-developed axial graben, sheet flows dominate, and hydrothermal activity with concomitant vent communities and biota are abundant. A cross-section across the graben here, as at the first topographic high, shows only pillow lavas outside the graben, fissuring near the graben wall, talus, collapse pits and flow-back structures in the graben close to the wall, and sheet flows and lava 'ponds' flooring the graben. Hydrothermal activity is found only within or at the walls of the graben⁹. These observations indicate that the sequence of eruptions in the graben must be sheet flows, followed by lobate flows, and finally by pillow lavas as the graben fills. Eventually, the ridge splits, a new graben is formed, and the cycle repeats.

The axial region north of the second topographic high at 11°30' N shows a marked transition as it becomes part of the OSC. Tectonically undisturbed lava formations are less abundant, pillow lavas and talus dominate, the axial graben shallows or pinches out, and hydrothermal activity is not seen. This contrasts markedly with the eastern limb of this OSC which shows active hydrothermal vents, recent sheet flows, and a well developed graben. We believe this limb is active and is propagat-

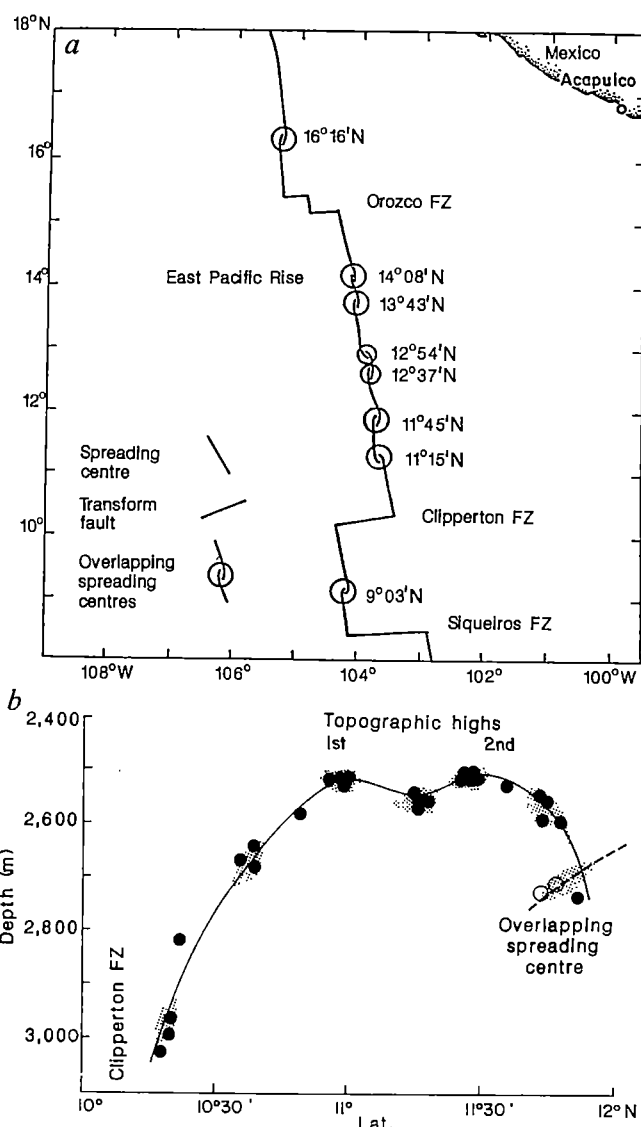

Fig. 1 a, EPR axis showing location of transform faults and conjugate (overlapping) spreading centres. The region studied in this work is the EPR axis from the Clipperton Fracture Zone to, and including, the OSC at 12° N. b, Axial depth versus latitude for the EPR 10°–12° N. The hatched areas are regions photographed using transponder navigation. ●, Dredge locations; ○, dredge locations in the east limb of the OSC. We placed transponders at seven discrete localities along the 180 km of EPR axis and performed detailed ANGUS¹⁴ photography over 4–7 km of the central axial region (see Fig. 1b for location of nets). This photographic coverage allowed us to delineate the axial graben and document such features as lava morphology, relative ages of eruptions, tectonic activity and hydrothermal activity. Using the transponder nets and information from the bottom photographs, we did carefully navigated dredging within the nets and within the neovolcanic zone, plus some dredging between nets using the SEABEAM bathymetry and conventional 12-kHz echo-sounding to guide the sampling (see Fig. 1b for sample location). In all, we made 14 ANGUS runs and 23 successful dredge hauls. About 70 samples initially selected as representative of type from each locality were analysed for major and trace elements by X-ray fluorescence spectroscopy at Woods Hole¹⁵, glass margins were analysed using an electron microprobe at the Smithsonian Institution¹⁶, and petrographic studies and mineral analyses were made on selected thin sections. These preliminary data are presented here.

ing southwards. The nodal basin between the overlapping limbs appears to be a passive feature. The walls are composed only of lava spillage or talus from the respective axes and the floor is covered with sediment, with only a few, old pillow lavas showing through the sediment (Fig. 2f). There appears to be no current volcanic activity within the OSC basin, and no tectonic activity or faulting suggestive of tensional or transform move-

Fig. 2 *a*, EPR axis near the Clipperton Fracture Zone showing typical pillow formations, often cracked. *b*, EPR axis a few kilometres north of *a* location, showing cracked and broken sheet-flow plates in axial graben. *c*, EPR axis about halfway between the Clipperton Fracture Zone and the first topographic high, showing an extinct hydrothermal vent with dissolving clam shells in collapsed lobate flow in the axial graben. *d*, EPR axis at first topographic high showing well developed and fresh sheet-flow formations on floor of axial graben. *e*, Hydrothermal 'smoker' near wall of axial graben on topographic high. Such vents are common on both axial topographic highs. *f*, Floor of nodal basin between the two axial limbs of the OSC at 12° N. The floor is undisturbed and sediment-covered with a few old pillow-lava formations showing.

ment between the limbs as previously suggested for such features¹⁰.

Various petrographic and chemical discriminants allow us to define five magma groups, A-E (Fig. 3). The lavas of magma groups B and C along this segment of the EPR show a systematic variation in Mg number ($\text{Mg}/(\text{Mg} + \text{Fe}) \times 100$) (Fig. 3*a*). With the exception of a few relatively 'primitive' members of magma group A, eruptives farthest from the topographic highs have lowest Mg numbers, suggesting possible cooling and fractionation as magma migrates along-rift. Group B basalts at the low point near the Clipperton Fracture Zone are apparently most fractionated, and there is a systematic decrease in the implied degree of fractionation approaching each topographic high. Basalts increase again in apparent degree of fractionation as the axis deepens into the large northernmost OSC. Both limbs of the OSC, including the tip of the propagating eastern limb, have these apparently fractionated basalts. The systematic compositional variation is reflected in covariances of most chemical components and by the modal mineralogy and mineral compositions. The most fractionated group B varieties, as inferred from Mg number, are moderately phyrlic basalt with up to 25% plagioclase, pyroxene, and minor olivine phenocrysts. Approaching the topographic highs the basalts become less phyrlic, only plagioclase and minor pyroxene or olivine are present, and An and Fo contents increase. Around the first topographic high the basalts are aphyric, and only minor plagioclase microphenocrysts are present. From 11°15' N to the second high, plagioclase plus olivine microphenocrysts are common, while pyroxene is present only near 11°15' N. The most phyrlic group C basalts (~15% plagioclase, olivine and pyroxene) are at the north end of the rift, in the overlap zone at about 11°50' N. Preliminary calculations indicate that on the first topographic high and along the southern limb to the Clipperton Fracture Zone, with the exception of a few basalts nearest the fracture zone, the basalts are comagmatic and simple low-pressure fractionation can be modelled using observed mineral and magma compositions. Similar relations have been demonstrated within the second topographic high and its axial limbs (W.B.B. and K.H., in preparation).

Some of the differences in both major- and trace-element chemistry of the five different magma types can be seen in Fig. 3. A plot of FeO versus MgO (Fig. 3*b*) shows consistent but subtle

differences between groups B and C, while the group of lavas near the Clipperton Fracture Zone (magma type A), and the magmas in the eastern limb of the OSC (magma type D) are clearly defined. Magma group E is found at two locations on the northernmost topographic high; it is characterized by large enrichments in incompatible elements compared with the other basalts from the EPR axis and is similar to transitional or enriched mid-ocean ridge basalts (E-MORB). The most distinctive chemical features of these five magma types are shown in Table 1.

Basalts of magma type A near the Clipperton Fracture Zone occur in the vicinity (same dredge haul) of other basalts belonging to magma type B. However, as noted in the photographic evidence, the axial region is badly broken up and different eruptive units and ages are in close proximity in fault scarps and talus. The basalts of magma type A show a wide range in degree of fractionation compared with the adjacent members of type B magma, which are all relatively fractionated. Compared with magma B, magma A shows lower Fe and higher Ti content for a given MgO concentration. Trace-element contents also are distinctive compared with magma type B, with lower Sr contents (see Fig. 3*c*), lower Zr/Y, and higher Zr/Nb ratios (see Fig. 3*d*). Langmuir and Bender¹¹ have previously noted that basalts erupted close to major transforms have different and unique compositions compared with adjacent axial basalts

Table 1 Chemical characteristics of different magma types along EPR axis 10°–12° N

	Type A	Type B	Type C	Type D	Type E
MgO (wt %)	5.5–7.4	5.6–7.2	6.4–8.1	6.1–6.8	6.6–7.4
FeO* (wt %)	10.9–13.2	10.4–13.8	9.2–11.9	12.2–13.7	9.4–10.0
TiO ₂ (wt %)	1.6–2.4	1.7–2.6	1.5–2.2	2.0–2.4	2.1–2.3
K ₂ O (wt %)	0.14–0.25	0.12–0.25	0.11–0.22	0.09–0.12	0.62–0.73
Sr (p.p.m.)	78–122	129–140	141–168	93–100	196–320
Zr/Nb	39–52	25–35	20–30	38–44	8.7–10.2
Zr/Y	2.4–3.2	2.9–3.0	3.0–3.3	2.5–2.7	4.1–4.6

* Total Fe as FeO.

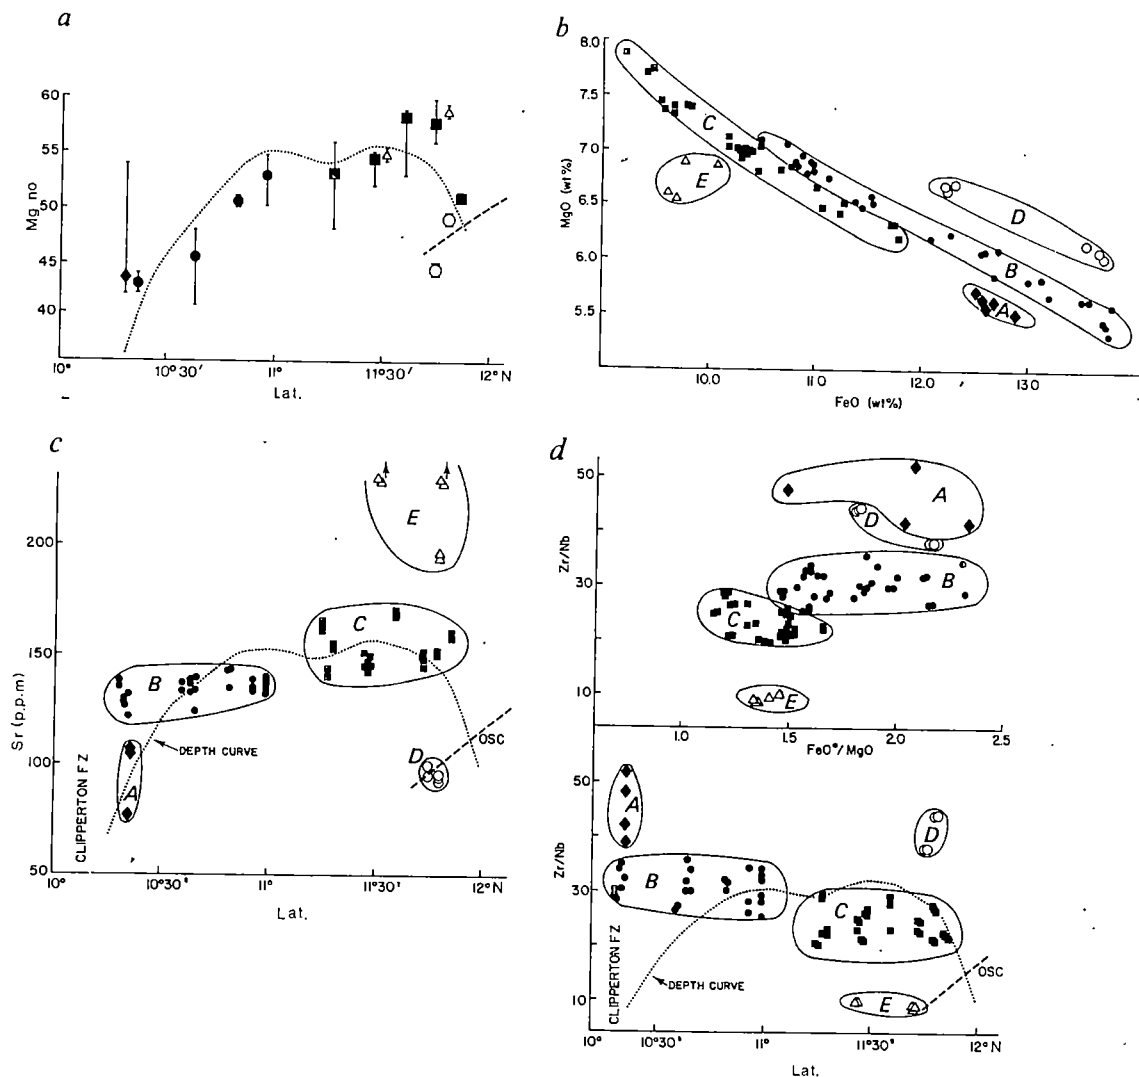

Fig. 3 *a*, Mg number ($\text{Mg}/(\text{Mg} + \text{Fe}) \times 100$) versus latitude along EPR axis 10–12° N. Symbols are mean Mg numbers, and the vertical line shows the range of Mg numbers at that location. *b*, MgO versus FeO for basalt glasses from the EPR axis. Five different groupings are noted as well as the range of FeO/MgO, indicating the degree of fractionation. *c*, Sr versus latitude for basalts from EPR axis. Five distinct magma types and their location are distinguished. *d*, Zr/Nb versus FeO*/MgO and latitude for basalts from EPR axis. ♦, A, near Clipperton Fracture Zone; ●, B, South axis and topographic high; ■, C, north axis, topographic high and west OSC; ○, D, eastern OSC; △, E, E-MORB. The dotted line in *a*, *b*, and *d* is the axial depth (see Fig. 1*b*).

and have referred to this as the “transform edge effect” (TFE). We are unsure without further analysis (such as isotopes, rare-earth elements, Ta, Th, and so on) whether magma type A is another example of a TFE or merely an older axial eruptive event unrelated to the present axial eruptives represented by magma type B.

Magma type B shows a wide range in degree of fractionation which decreases systematically towards the topographic high. This is in agreement with the model suggesting major input to a master magma chamber beneath the topographic high. Lateral injection along-ridge (probably sub-crustally) from the chamber with concomitant crystallization as the magma moves into cooler crust, is a reasonable explanation which is also consistent with recent observations in Iceland¹². All the basalts from magma type B are normal MORB, as are those from magma type C from the second topographic high. Single specimens from either magma probably could not be discriminated as different types, but the large number of samples analysed here with high precision show small but consistent differences in both chemistry and modal phase proportions between the two main magma types B and C which persist across substantial variations in fractionation. Mineralogically, magma type B has plagioclase and pyroxene with little olivine, whereas magma type C has both olivine and plagioclase as phenocrysts but little pyroxene. Magma type B generally has higher Fe and lower Ti content for a given MgO concentration, and also has lower Sr contents,

lower Zr/Y ratios and higher Zr/Nb ratios compared with magma C (Fig. 3*b–d*). The differences between magma B and C are small and compositional ranges overlap. However, comparisons of trace-element ratios versus Mg number or FeO/MgO ratio show that the magmas are distinctly different in composition.

The topographic low between the axial highs is apparently filled with type C lavas, suggesting that the southward propagating limb of the northern high has almost closed this small OSC. The northernmost limb of the rift containing magma type C also becomes increasingly fractionated but as the distances are not so great, and the tip of this limb is apparently not active, the degree of fractionation is not so pronounced as on the long southern limb of the first topographic high of magma type B.

The magmas from the active eastern limb of the OSC, magma type D, have quite unique compositions compared with the main lavas of types B and C; they resemble group A in some but not all features. They have higher Fe and Ti contents for a given MgO concentration, low K and Sr content, low Zr/Y and high Zr/Nb ratios. They are phryic basalts in which olivine is a prominent phenocryst and include some varieties which are quite fractionated, but we are unsure whether they are fractionated extremities of lavas from the main chamber near 12°30' N, or lavas showing a TFE effect since they are at the tip of a propagating rift breaking into old, colder crust¹³.

Magma type E lavas, the so called E-MORB, were recovered

Fig. 4 Five magma types observed along EPR axis 10°–12° N. Dotted areas indicate >8% mineral phenocrysts. Magma type E is presumed to be an off-axis (4 km) seamount from which lavas have intruded into the axial region at two locations. It is uncertain whether magma type D is a unique magma batch like magma type A, near the propagating rift tip, or the proximal tip of a down-axis injection from a magma chamber near 12°30' at the next axial topographic high.

at two localities on the second topographic high. A previous cruise by the French *N.O.J. Charcot*⁷ in the same general area also recovered samples of E-MORB from the axial graben and from the eastern rim of the axis near 11°27' N. We recovered two samples about 20 km away in the northern part of the axis approaching the tip of the west limb of the OSC. R. Hekinian provided splits of the French samples which we analysed; these are E-MORBs similar to those we recovered. The type E lavas have higher Ti and lower Fe content for a given MgO concentration compared with the other axial lavas. They have very high concentrations of incompatible elements such as K, Sr, Zr and Nb, and higher Zr/Y and lower Zr/Nb ratios than the other magma types. The *Charcot* surveys have shown that at this latitude, about 11°45' N, there is a large seamount only about 4 km to the west of the ridge axis which is erupting various types of lavas (R. Hekinian, personal communication). Available data are not sufficient to determine whether lavas from this seamount may have been injected transversely, or whether they flowed on the sea floor from the seamount to the present EPR axis.

Conclusion

Figure 4 shows diagrammatically the distribution of the five magma types. Our observations support the Francheteau-Ballard model of axial processes. We suggest that the topographic highs are the locus of magma upwelling into magma

chambers, and that magmas are injected down the axes from these localities. These lavas show systematic changes in composition along the axis. In essence, the EPR is made up of a series of volcanoes separated by transform or non-transform (OSC) offsets. This is analogous to the observations of central volcanoes located along the rift zone in Iceland which have been shown to inject magma, subcrustally, up to 70 km along rifts from the central volcano; this injection often is highly asymmetric as in these EPR examples¹².

We have shown that the depression between the overlapping limbs of an OSC is old and inactive. We have demonstrated that the eastern limb of the OSC at 11°45' N is very active and propagating southward. Our data indicate that lavas at the propagating tip of an overlapping pair of rifts, or close to a large transform, may have distinct chemical compositions. Our observations also suggest local chemical heterogeneity in the mantle that must give rise to the pronounced differences between axial and nearby seamount lavas. We also observe small-scale mantle heterogeneity or differences in melt formation, local plumbing or magma mixing that give rise to the distinct compositions observed between individual magma centres or volcanoes along axis. These differences are superimposed on compositional variation which can be produced by the fairly extensive fractionation which has occurred within each magma batch. Further aspects of these differences and the nature of the source regions are currently being investigated by isotope and rare-earth element analysis and geochemical modelling. Although a variety of magma compositions have been noted in samples recovered previously from the EPR, this is the first documentation of systematic variation in lava composition and morphology that can be ascribed to specific axial processes and their relative position in time and space.

We thank the officers, crew and technicians of R/V *Melville* for assistance, and Rob Zierenberg (USGS) for help in dredging. We thank Brian Schroeder, Margaret Sulanowska and Tim O'Hearn for help in the analysis of the samples. J. Marsh and M. Harvey typed the manuscript. The manuscript benefitted from reviews by R. Hekinian. This work was supported by NSF grant OCE83-09977. This is contribution no. 5962 from the Woods Hole Oceanographic Institution.

Patterns of *engrailed* and *fushi tarazu* transcripts reveal novel intermediate stages in *Drosophila* segmentation

Michael P. Weir & Thomas Kornberg

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, USA

Transcripts of the engrailed and fushi tarazu genes in young Drosophila embryos are initially patterned in intervals larger than a single segment. The segmental pattern evolves in a stepwise sequence through successively smaller spatial units.

THE *Drosophila* embryo is spatially organized into repeating units—the anterior and posterior developmental compartments¹ of each metameric segment. These compartment types alternate in a striking zebra-like pattern as transverse encircling bands of cells on the surface of the young embryo^{2,3}. Their presence is

not apparent from the embryo morphology, but is revealed by cell lineage studies^{4–6}, and by *in situ* identification of cells that express the *engrailed* locus. The *engrailed* locus is expressed only in the posterior compartment cells².

The *engrailed* gene is one of a number of genes whose function

Fig. 1 Micrographs showing *engrailed* transcripts in blastoderm stage embryos. Bright-field (left) and corresponding dark-field (right) micrographs were recorded after hybridization with an *engrailed* cDNA probe and autoradiography. Sections in all figures are oriented anterior left. *a, b*, Section of embryo at nuclear cycle 13 with no detectable localization of autoradiographic grains. *c, d*, Early cycle 14 embryo, oriented ventral down, with nuclei beginning to elongate. Ten such sections were found with grains most prominently over the nuclei that later will correspond to the second of the 14 stripes (Fig. 2*f*). In this section, sparse concentrations of grains are also over the nuclei of what are probably stripes 4, 8 and 12 (arrowheads). *e, f*, Horizontal section. The nuclei have elongated and membrane furrows have extended into the cytoplasm just beyond the nuclei. A prominent autoradiographic signal is over the nuclei and cytoplasm of stripe 2. Scale bar, 50 μ m.

Methods. Embryos were dechorionated with 2.5% sodium hypochlorite for 3 min, fixed in 2% paraformaldehyde, 0.5 \times phosphate-buffered saline (PBS) and 50% *n*-heptane for 15 min using vigorous shaking, and transferred to 45% methanol, 25 mM

EGTA, 50% heptane and shaken on dry ice for 10 min. Vitelline membranes were then removed by rapid heating to 40 $^{\circ}$ C²⁷. Following three washes in 90% methanol, 50 mM EGTA, embryos were transferred in stages to PBS, before embedding in O.C.T. (Miles Scientific) using liquid nitrogen. *In situ* hybridizations onto 8 μ m frozen sections were performed as described previously using tritiated nick-translated DNA probes of the p9-1.4 cDNA². Embryonic stages: Observation during nuclear cycles 10-13, syncytial blastoderm stages, shows that at cycle 10, yolk nuclei stop dividing, pole cells bud from posterior end, and remaining nuclei appear on the surface and divide in near synchrony. At cycle 14, cellular blastoderm stage, there is a ~90 min period of mitotic quiescence during which membranes form between the peripheral nuclei and gastrulation begins. Embryos in the sections were staged by counting nuclei in 100- μ m intervals along the embryo periphery. 43 measurements of cycle 14 embryos yielded a value of 15.6 ± 1.4 nuclei per 100 μ m. The values used for other stages were: cycle 10, 4 nuclei; cycle 11, 6 nuclei; cycle 12, 8 nuclei; and cycle 13, 11 nuclei.

is essential for segmentation. The gene *fushi tarazu* (*ftz*) is another⁷, and it is expressed in the young embryo in seven evenly spaced bands of cells with a two-segment periodicity⁸. Although each band has the width of one segment⁹, the spatial relationship between the bands of *ftz*-expressing cells and the metameric segments is not known. Nevertheless, the expression of *engrailed* and *ftz* both provide indications of the timing and nature of the processes that subdivide the embryo into equal-sized metameres, and they provide molecular markers that can be used to follow the process of segmentation.

In this study, the generation of the *engrailed* and *ftz* patterns of expression have been determined by *in situ* hybridization. The use of fixation methods that better preserve the morphology of the early *Drosophila* embryo and longer autoradiographic exposures have yielded a more precise portrayal of the generation of the segmental patterns and have revealed several new aspects of segmentation. Transcription patterns for both *engrailed* and *ftz* suggest that subdivision of the embryo proceeds through a sequence of intermediate stages, each stage part of a process that partitions the embryo into progressively smaller units.

Expression of *engrailed* in early embryos

After fertilization and nine synchronous mitotic divisions, three types of nuclei can be distinguished in the *Drosophila* (cycle 10) embryo: approximately 100 centrally located yolk nuclei, about 450 peripheral nuclei at the embryo surface that will generate the somatic tissues, and about 12 future germ cells at the posterior pole¹⁰⁻¹⁴. Four divisions of the peripheral nuclei follow. During the 14th cell cycle, the nuclei, initially round,

elongate before membrane furrows invaginate from the surface of the embryo to separate the nuclei into individual cells¹⁵. During this period the nuclei become highly active in transcription^{16,17} (A description of relevant embryonic stages is given in Fig. 1 legend.)

To identify nuclei that express the *engrailed* locus, wild-type embryos were fixed and quick-frozen for preparation of cryostat sections. After hybridization with radiolabelled probes generated from an *engrailed* cDNA clone², autoradiographs were exposed for 3-4 months to detect *engrailed* transcripts. Sections from embryos younger than stage 14 did not have grains localized either over nuclei or in any other distinctive pattern (Fig. 1*a, b*), yet the grain density over such embryos was consistently higher than background. Since Northern blot analysis of RNA isolated from cleavage stage and syncytial blastoderm stage embryos has revealed the presence of *engrailed* transcripts¹⁸, these early transcripts are either not regionally localized or our *in situ* hybridization methods lacked sufficient sensitivity for definitive detection.

As the embryo matures through the 14th division cycle, striking changes in *engrailed* expression produce a pattern of 14 equally spaced and equally dense stripes (Fig. 2*f*). The pattern is generated in a reproducible and recognizable sequence. Anterior bands appear before posterior ones, ventral bands before dorsal ones (Figs 1, 2). However, superimposed on this anterior to posterior sequence of appearance are strong but transient periodicities in the density of autoradiographic grains over the different bands: (1) the first two prominent bands in the ventral region are bands 2 and 8; (2) bands 4 and 8 become prominent before band 6, and band 12 before 10, suggesting a

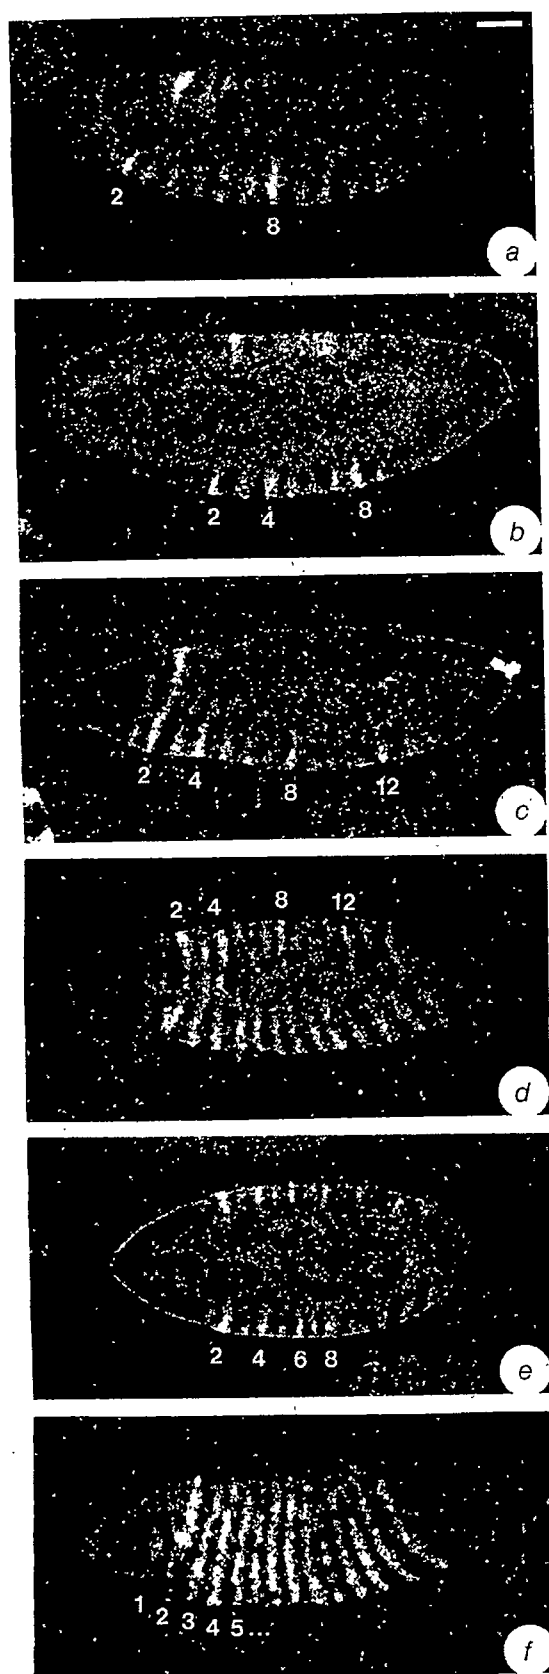

Fig. 2 Micrographs of *engrailed* transcripts in early gastrulas. Dark-field micrographs of embryos oriented ventral down except for *e*, a horizontal section. Stripes are more prominent in the anterior and ventral portions. Most prominent stripes are: *a*, ventral 2 and 8, dorsal 2; *b*, ventral 2, 4 and 8, dorsal 2; *c*, ventral 2, 4, 8 and 12, dorsal 2; *d*, ventral 2-14 and dorsal 2, 4, 8 and 12; *e*, lateral 2, 4, 6, 8, 10, 12; *f*, all stripes approximately equal. Note that among the weak stripes between 4 and 8 in *b*, stripe 6 is the weakest. *a* Has a two-band pattern, *b*-*d*, four-segment periodicity, and *e*, a two-segment periodicity. Scale bar 50 μ m.

Fig. 3 The order of appearance of the even-numbered bands of *engrailed* hybridization was determined in 247 section edges from 132 sections of 105 different embryos. Section edges chosen for examination were those with clear differences in band intensities. After a pairwise comparison of each of the even-numbered bands, only cases of clear intensity differences were tabulated. *b*, Total number of instances in which two bands with different intensities were compared; *a*, the percentage of such comparisons in which the bands designated along the horizontal axis were more intense than those indicated on the vertical axis. The boxed numbers indicate cases of posterior stripes appearing before anterior ones: 8 before 6 and 12 before 10. *c*, A summary of the types of patterns that were observed. Embryos of increasing age are portrayed as rectangles with their posterior pole to the right. The dotted areas indicate bands of hybridization.

four-segment reiterated pattern; and (3) when all of the even-numbered bands become prominent, they have autoradiographic signals that are briefly stronger than those of the intervening odd-numbered bands, suggesting a two-segment reiterated pattern. A detailed description of this progression follows.

The first of the prominent bands of hybridization was observed in early cycle 14 embryos whose nuclei had just initiated the elongation process (Fig. 1*c, d*). A stripe of grains with a width of one to two nuclei was oriented perpendicular to the long axis of the embryo, about one-third from the anterior end. Grain density was initially greater over the nuclei than over the adjacent cytoplasm (Fig. 1*c, d*), but during the 14th cycle, the relative proportion of cytoplasmic grains increased (Fig. 1*e, f*). With the commencement of gastrulation near the end of cycle 14, the stripe of hybridization was at the posterior edge of the cephalic furrow, and corresponded to the second of the 14 stripes from the anterior end (Fig. 2*f*). The posterior edge of the cephalic furrow is the position of the mandibular or maxillary head segment primordium^{9,19}.

The fourth and eighth bands, weak concentrations of grains at the beginning of cycle 14 (Fig. 1*c, d*), were (along with band 2) consistently the most intense as gastrulation began (Fig. 2*a-d*). The relative strengths of the autoradiographic signals over the fourth and eighth stripes were often unequal (82 cases). In such sections in which the ventral and dorsal surfaces could be unambiguously identified, band 4 was more intense than band 8 dorsally (19/19 cases), and band 8 was more intense ventrally (13/16 cases) (Fig. 2*a*). Thus, ventrally, band 8 appeared before 4, and dorsally, band 4 appeared before 8. Band 12 was also observed as a prominent early autoradiographic signal (Fig. 2*c, d*), although with less regularity.

Fig. 4 Micrographs of *engrailed* transcripts in *engrailed* mutants. *a*, Dark-field micrograph of a section of a gastrulating wild-type embryo. The grains of adjacent stripes are approximately equal in density (also see Fig. 2*f*). *b*, Dark-field micrograph of a section of an *en^{C2}/en^{SF31}* mutant embryo during germ-band elongation (*en^{SF31}* deletes the entire *engrailed* locus). Signal alternates in strength in adjacent segments and the phasing is the same as observed in younger wild-type embryos: prominent stripe 2 is located in the posterior part of the cephalic furrow (arrow). *c*, *e*, Bright-field and dark-field images of a wild type embryo following germ-band shortening. The signal strengths are approximately equal over adjacent segments. Note the grains over the anterior portion of the ventral nerve chord (arrows in *c*). Serial sections of the embryo revealed labelling over the other ventral nerve chord ganglia. Such expression is consistent with earlier reports that *engrailed* function is essential in the adult nervous system²⁸. *d*, Bright-field micrographs of a section of an *en^{LA4}/en^{LA7}* mutant embryo. Pairs of segments are fused such that deep grooves are only observed every second segment (arrows). *f*, *g*, Higher magnification views of the periphery of the mutant in *d*. Grains are over every second segment over the deep grooves (arrows). Few or no grains are over the sites of the segment fusions. *h*, Dark-field micrograph of the ventral cuticle of an 18-h wild-type embryo. Note the mouthparts (M), eight abdominal denticle bands, and posterior spiracles (S). *i*, Dark-field micrograph of the ventral cuticle of an *en^{LA4}/en^{SF31}* embryo. Fused abdominal denticle belts are indicated. Scale bars, 50 μ m in *a-e*; 25 μ m in *f*, *g*; and 100 μ m in *h*, *i*.

In 18 sections with intense labelling in bands 4 and 8 or 8 and 12, the strengths of the bands in the three-band interval between them varied such that the intervening odd-numbered bands were more intense than the even-numbered ones (Fig. 2*b*).

To document the order of appearance of these even-numbered bands, sections whose bands varied in intensity were examined. In 132 such embryo sections, pairs of even-numbered bands were compared and instances of clear differences in intensity were scored (Fig. 3). Band 2 was almost always more intense, and with only two exceptions, the more anterior bands were more intense than each of the posterior bands. As exceptions, the 8th was usually more intense than the 6th and the 12th more than the 10th (Fig. 3*a*, *b*). A pictorial representation of embryos with the implied four-segment periodic patterns is presented in order of increasing complexity and maturity (Fig. 3*c*, see also Figs 1*d*, 2*b-d*).

Even-numbered autoradiographic stripes increased in intensity throughout the 14th cycle. Between these were stripes with less intense signals. The resulting pattern, most prominent at the beginning of gastrulation, had a two-segment periodicity with alternating strong and weak autoradiographic signals over adjacent segments (Fig. 2*e*). The autoradiographic grains of the more intense even-numbered bands were dense over both the nuclear and cytoplasmic regions; in contrast the less intense odd-numbered bands were predominantly labelled over the nuclei.

The alternating pattern leads within minutes to an arrangement of stripes with equal intensity. The equalization process

occurred with an anterior to posterior and a ventral to dorsal progression. As gastrulation proceeds, the ventral germ band extends around the posterior end onto the dorsal surface. In sections of germ band elongation embryos, additional bands of hybridization in the head and posterior regions were observed as reported previously². By this stage, all of the stripes were two to three cells wide and were equally intense. Consistent with previous descriptions, cells expressing the *engrailed* locus were observed in the progenitors of the mesoderm and nervous system throughout the germ-band elongation stages. However, the improved preservation of sections and longer exposures revealed, in addition, expression in each segmental ganglion of the embryonic nervous system during later stages (Fig. 4*c*).

Expression of *fushi tarazu* in early embryos

Gene expression in a pattern with reiterated periodic bands was first described for the *fushi tarazu* locus⁸. To compare the processes that generate the patterns of *engrailed* and *ftz* expression, embryo sections were hybridized with a *ftz* probe in parallel to the experiments described above for the *engrailed* gene. Our results largely confirm the work of Hafen *et al.*⁸, but reveal two additional intermediate stages in the temporal and spatial pattern of *ftz* expression—generally dispersed transcription at nuclear cycle 10 and a four-band stage early in cycle 14.

Localization of *ftz* RNA was first detected in syncytial blastoderm embryos during their 10th nuclear division cycle. Autoradiographic grains were localized over both yolk and

Fig. 5 Patterns of *fushi tarazu* transcripts in syncytial and cellular blastoderm stage embryos. *a, b*, *ftz* transcripts were detected over peripheral (P) and yolk nuclei (Y) at cycle 10 (arrows in *a* and *b*). The bright-field micrograph is a high-magnification image of the section shown in dark-field in *b*. Arrows point to corresponding nuclei. Arrowhead in *a* points to an unlabelled nucleus. Arrowheads in *b* point to examples of labelled peripheral nuclei. *c, d*, Embryo at cycle 12. During cycles 11–13, *ftz* transcript is evenly distributed over the middle portion at the edge of the embryo as previously reported⁸. *e, f*, Cycle-14 embryo; *ftz* transcripts are in four broad bands. *g, h*, Cycle-14 embryo with membrane furrows extended just beyond the nuclei; *ftz* transcripts are in seven bands. The probe was pDmV61H3.5 (a genomic 3.5 kilobase pair *Hind*III subclone in pUC8²⁹), nick-translated with tritiated nucleotides. Scale bar, 25 μ m in *a*, and 50 μ m in *b–h*.

peripheral nuclei (Fig. 5*a, b*). Labelled nuclei were along the entire egg length, although not all peripheral nuclei were labelled. By the 12th cycle, *ftz* RNA was uniformly distributed in the cortical region of the embryo, from approximately 15% to 65% egg length (Fig. 5*c, d*). No further regional localization of the hybridizing RNA was observed until the 14th cycle, when autoradiographic grains were in discrete regions that approximate four broad bands (Fig. 5*e, f*). The most anterior band was not as wide as the others, but as the nuclei elongate and before the membrane furrows penetrate into the embryo, the three posterior broad stripes subdivided and yielded a pattern of seven discrete regions of hybridization (Fig. 5*g, h*). At both the four- and seven-band stages, the discrete gaps that define the bands appeared in an anterior-to-posterior and ventral-to-dorsal progression. There was no apparent difference in density of autoradiographic grains over the different stripes. In stage 14 embryos *ftz* transcripts were more numerous than *engrailed* as estimated from grain densities after *in situ* hybridization.

The existence of the transient four-band stage was documented by tabulating the order of appearance of gaps between hybridization stripes. With only three exceptions, the gaps defined the more anterior stripes first. These exceptions were: the gap between stripes 3 and 4 formed before the stripe 2–3 separation, and the gap between stripes 5 and 6 formed before the stripe 2–3 and stripe 4–5 separations (Fig. 6). Figure 6*c* summarizes the implied progression of *ftz* expression from uniform to banded distribution.

To establish the relationship between the stripes of *ftz* and *engrailed* hybridization and the segment primordia in the blastoderm, the repeat lengths of the various periodic patterns were

compared. In sections of early stage 14 embryos in which the gaps between bands of *ftz* transcript were developing, the distance between gaps 1–2 and 3–4, and between gaps 3–4 and 5–6 was $88 \pm 11 \mu\text{m}$, corresponding to 13.8 ± 1.8 adjacent nuclei (56 measurements were taken). In sections of early stage 14 embryos hybridized with the *engrailed* probe, the distance between prominent bands 4 and 8, and between 8 and 12 was $92 \pm 11 \mu\text{m}$, corresponding to 14.4 ± 1.7 adjacent nuclei (46 measurements). Thus, the intervals of *engrailed* expression defined by bands 4, 8 and 12 have the same periodicity as the initial gaps of *ftz* expression. Given the estimated segment width of 3–4 cells⁹, this periodicity corresponds to four segments. As described previously^{2,3,8}, later cycle 14 embryos with 14 stripes of *engrailed* and 7 stripes of *ftz* expression have periodicities that correspond to one and two segments, respectively.

Throughout the syncytial blastoderm and cellular blastoderm stages, the autoradiographic grains of *ftz* hybridization were most concentrated over the periplasmic region between the nuclei and the embryo cortex. This sequestration of *ftz* RNA contrasts with the more generally dispersed *engrailed* RNA and may suggest novel mechanisms for the regulation of RNA storage and utilization.

Transcript localization in *engrailed* embryos

All developmental stages^{18,20–22} are affected by *engrailed* mutations. The *engrailed* cells in mosaic adults develop abnormally in all posterior compartments and generate similar types of defects in each segment^{20–24}. Yet mutant embryos have fused pairs of segments, and very occasionally, fusions of groups of four segments (Fig. 4*h, i*)²². A gene such as *engrailed* that is

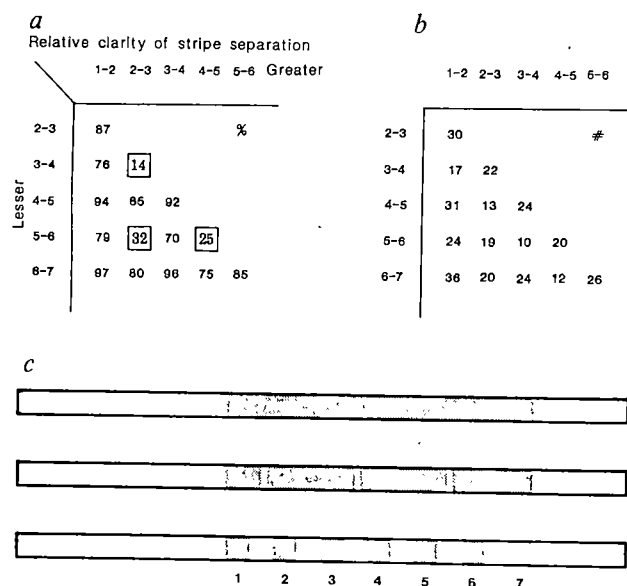

Fig. 6 The order of appearance of gaps in *ftz* expression along the embryo periphery was determined in 68 section edges from 34 sections. Sections chosen for analysis had gaps of varying clarity. For each comparison of two gaps, part *b* indicates the total number of cases with differences in the clarity of the gaps and part *a* indicates the percentages of such comparisons in which the gaps designated along the horizontal axis were more pronounced than the gaps on the vertical axis. The boxed figures indicate cases of posterior gaps becoming pronounced before anterior ones. *c*, A summary of the types of patterns observed. Embryos of increasing age are portrayed as rectangles with their posterior pole to the right. The dotted areas indicate regions of hybridization.

expressed in every segment might be expected to affect all segments similarly, whereas pairwise segment fusions might be expected in mutants of genes required in every second segment²⁵. Thus the *engrailed* embryonic phenotype was surprising. We now demonstrate a direct correlation between the fusion phenotype of *engrailed* mutant embryos and the expression of the *engrailed* gene in periodic, two-segment-wide intervals.

Sections of *engrailed* mutant embryos were hybridized with the *engrailed* complementary DNA probe. Mutants examined were *en*^{LA4}/*en*^{LA7} heterozygotes (both apparent point mutations), and *en*^{C2} (an inversion breakpoint within the *engrailed* locus approximately 15 kilobase pairs upstream of the transcription unit (B. Drees and T.K., unpublished)) hemizygotes²². Mutants were identified in sections by their abnormal morphology and abnormal distribution of *engrailed* transcripts. Whereas in wild-type embryos the intensity of hybridization to the posterior compartment stripes alternated for a brief period in the cellular blastoderm and early gastrula and was uniform thereafter (Figs 2*f*, 4*a*, *c*, *e*), in most mutant embryos the alternating intensity persisted through germ-band elongation and germ-band shortening (Fig. 4*b*, *d*, *f*, *g*). The identities of the more prominent stripes in the mutant embryos corresponded with the location of the more intense stripes of hybridization of younger wild-type embryos; for example, the stripe at the posterior edge of the cephalic furrow was prominent in both (arrow in Fig. 4*b*). Comparison of the phasing of the alternating transcriptional pattern with the fused segment morphology of the mutants indicated that the weaker stripes of the alternating pattern coincide with the positions of the segment fusions (Fig. 4*d*, *f*, *g*).

Thus, apparent point mutations or breakpoint mutations upstream of the transcription unit both affect the spatial and temporal pattern of *engrailed* expression. This demonstrates that DNA 5' to the transcription unit is involved in transcriptional regulation and that the *engrailed* function may modulate its own expression, either by directly affecting transcription or through interactions with other regulatory factors.

Discussion

The surface of the *Drosophila* cellular blastoderm is uniform in appearance, but its constituent cells are not equivalent. These studies and previous work⁸ have shown that during the 14th nuclear division cycle, the blastoderm cells differentiate to express selected genes in remarkably precise patterns. Maturation of the expression patterns of the *engrailed* and *ftz* genes have provided two views of this differentiation process, a process that progressively subdivides the embryo into biochemically and spatially distinctive portions.

Apparent differences between the development of the *engrailed* and *ftz* patterns of expression include earlier maturation of the *ftz* pattern and contrasting modes for generating bands of expression: new bands of *engrailed* expressing nuclei seem to be added while *ftz*-expressing nuclei are suppressed in a patterned arrangement. However, direct comparisons between the patterns of *engrailed* and *ftz* RNA are made difficult by the lower abundance of the *engrailed* transcripts. The presence of *engrailed* transcripts in cleavage and syncytial blastoderm stages has been demonstrated by Northern analysis¹⁸, but the low-level expression, which may be generally dispersed or distributed in a portion of the embryo, was not detectable with our *in situ* hybridization methods. The appearance of the *engrailed* patterns in *in situ* autoradiograms may be delayed until transcript levels are sufficient to be detected by our assay. Therefore, the great quantitative difference between levels of *ftz* and *engrailed* transcripts may mask fundamental similarities.

For both *engrailed* and *ftz*, the mature pattern of equally sized and equally spaced stripes of expressing cells emerges from patterns with longer repeat lengths that define fewer units. Maturation proceeds with anterior to posterior and ventral to dorsal polarities. For *ftz*, expression progressively narrows to four broad bands with a four-segment repeat length before dividing into seven narrower ones with a two-segment-repeat length. For *engrailed*, bands one to two cells wide define long intervals that shorten in a stepwise manner—first two bands (2 and 8 ventrally), then a four-segment periodicity, then two, and then in one-segment intervals.

That reiterated patterns of expression progress from longer to shorter repeat lengths suggests that the process of segmentation involves progressive partitioning of large units into smaller ones. The existence of discrete intermediate stages of segmentation has been proposed previously on theoretical grounds²⁶, and is strongly supported by the pattern of *engrailed* expression in *engrailed* mutants. Mutant late gastrulas had *engrailed* transcripts in patterns characteristic of younger embryos—in intervals greater than a single segment—indicating that the segmental fusions of *engrailed* mutants may be relics of earlier developmental units. A similar conclusion was drawn earlier from the phenotypes of the 'pair-rule' segmentation mutants that affect homologous portions of every second embryonic segment. It was suggested that such phenotypes are indicative of the transient existence of double-segment-sized units or fields²⁵.

The sequence in which the spacing of segments in the embryo is defined eliminates several possible mechanisms of segmentation. It indicates that the precisely spaced rows of cells in each segment are not designated in a simple sequential fashion at some predefined interval along the embryo's longitudinal axis. Nor do the many elements of the pattern appear simultaneously in their final form. Rather the mature pattern seems to involve proportioning of the embryo into successively smaller units. Such proportioning may provide the basis for coding position along the embryo's longitudinal axis. The overlapping activities of genes expressed with periodicities of one segment, two segments and larger intervals, together could direct in a combinatorial way the development of the blastoderm cells.

This work was supported by a fellowship from the Jane Coffin Childs Memorial Fund for Medical Research to M.P.W. and a NIH grant to T.K. We thank M. Scott for providing the *fushi tarazu* genomic clone, T. Karr and M. Simon for technical advice, and S. Poole and G. Martin for helpful comments on the manuscript.

Transcription pattern of the *Drosophila* segmentation gene *hairy*

P. W. Ingham, K. R. Howard & D. Ish-Horowicz

Developmental Genetics Laboratory, Imperial Cancer Research Fund, Mill Hill Laboratories, Burtonhole Lane, London NW7 1AD, UK*

Segmentation of the Drosophila embryo requires expression of the pair-rule genes, mutations of which cause reiterated deletions in alternate segments along the antero-posterior body axis. We find that transcripts of one such gene, hairy, accumulate in eight distinct regions of the early embryo. This pattern of expression is compared with that of another pair-rule gene, fushi tarazu, and its dependence on maternally expressed genes is described.

A COMMON theme in the organization of many metazoa is the subdivision of the body into a series of homologous segments¹. Different structures are then elaborated in the various segments to generate complex forms. A vivid example of such segmental or metamer organization is provided by the insects. Although segmentation of the insect body has been studied for many years²⁻⁴, the prospect of an understanding at the molecular level has only recently come into view with the identification, in *Drosophila melanogaster*, of most of the genes required for the process⁵⁻⁹.

Metameric organization is established during early *Drosophila* embryogenesis¹⁰⁻¹² as the incipient cells of the blastoderm embryo respond to information generated epigenetically in the maternally derived environment of the egg^{13,14}. This response depends on the expression of the zygotic genome and, in particular of genes defined by a class of zygotically acting mutations⁵⁻⁸ which disrupt the generation of the normal segmental pattern. These fall into three distinct phenotypic classes: (1) the gap mutations, which cause the deletion of contiguous groups of segments, (2) the pair-rule mutations, which result in deletions of homologous pattern elements in alternate segments, and (3) the segment polarity mutations, which affect the patterning of every segment.

The discovery of the pair-rule class provided the first evidence of a double-segment order during the formation of the metameric pattern⁵. This order is reflected at the molecular level by the pattern of expression¹⁵ of the pair-rule gene *fushi tarazu* (*ftz*)^{16,17}. At the blastoderm stage, *ftz* transcripts accumulate in seven discrete regions which repeat along the antero-posterior axis of the embryo with double-segment periodicity¹⁵. Such a precise pattern of transcript distribution implies that the *ftz*⁺ function is specifically required for the establishment of particular metameric units—those which are deleted in *ftz*⁻ mutants. Mutants of a second pair-rule gene, *hairy*(*h*)^{5,18}, cause a pattern of deletions which is approximately complementary to that typical of *ftz*, suggesting a corresponding complementarity of spatial expression and function.

We have analysed the spatial distribution of *h* RNA in early embryos, and compare it with the previously described *ftz* transcription pattern. We also show that establishment of the *h* transcription pattern depends on maternal determinants of both antero-posterior and dorso-ventral polarity.

Effect of *hairy* on embryonic segmentation

The metameric organization of the *Drosophila* body is directly reflected in the cuticle of the first-instar larva. This is especially clearly illustrated by the pattern on its ventral surface (Fig. 1 and ref. 19). Each thoracic and abdominal segment secretes a characteristic belt of cuticular processes or denticles. The metameric origin of the mouthparts is obscured by head involution, but cuticular structures characteristic of each segment can be easily identified.

Larvae homozygous for *h* null mutations exhibit a range of segmentation defects¹⁸ representing variations on a common theme, the pair-rule phenotype. The most regular *h* phenotype (Fig. 1c) consists of the deletion of the anterior region of each even-numbered abdominal segment and the posterior region of each odd-numbered abdominal segment from the larval cuticular pattern. This is almost the precise complement of the phenotype characteristic of amorphic alleles of the pair-rule gene *ftz* (Fig. 1d). In both cases, the same register of deletions extends into the thoracic and head segments (Fig. 1a). In *h* mutants, structures which derive from the mandibular (G1) and labial (G3) segments (the ventral arms of the cephalopharyngeal skeleton and H-piece respectively)²⁰ are deleted. In addition the medial tooth, a derivative of the labrum, is disrupted. This contrasts with the phenotype of strong *ftz* alleles in which only derivatives of the post-oral maxillary and labial segments are affected.

This regular pair-rule phenotype is typical only of a proportion of animals homozygous for any given amorphic *h* allele¹⁸. Commonly, more extreme defects are seen. The entire third thoracic segment is often deleted such that the second thoracic and first abdominal denticle bands fuse; similarly the remaining three posterior abdominal bands frequently fuse to form a continuous 'lawn' of denticles exhibiting polarity perturbation^{18,21}.

These lesions in the larval cuticle are manifestations of defects occurring much earlier during embryogenesis. Absence of *h*

* New address from December 1985: ICRF Developmental Biology Unit, Department of Zoology, University of Oxford, South Parks Road, Oxford OX1 3PS, UK.

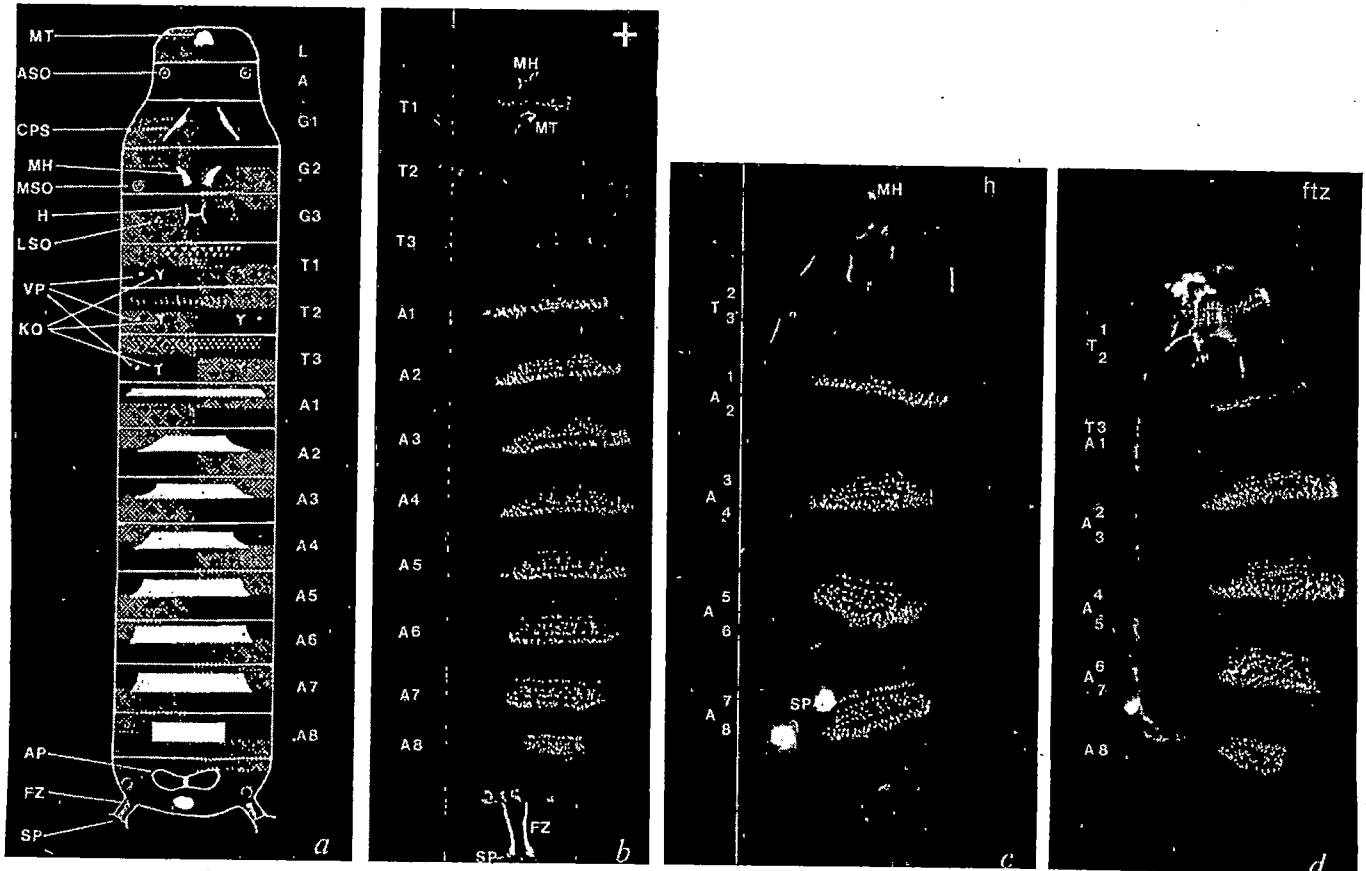

Fig. 1 *a*, Schematic representation of a first-instar *Drosophila* larva. The cephalon and mouthpart segments are drawn as they would appear in the absence of head involution. Each thoracic and abdominal segment is characterized by a ventral denticle band, represented by white bands. The thoracic segments each bear a pair of ventral pits (VP) and Keilin's organs (KO) which probably mark the position⁴⁰ of the antero-posterior compartment⁴¹ boundary. The thoracic segments each differentiate specific structures: LSO, labial sense organs; H, H-piece; MSO, maxillary sense organs; MH, mouth hooks; CPS, cephalopharyngeal skeleton. Anterior to these are the antennal sense organs (ASO) and the medial tooth (MT) of the labrum (see ref. 20). The hatched regions represent the consensus deletions typical of either *h* (left) or *ftz* (right) mutations (see *c* and *d*). *b*, Ventral cuticle of a first-instar larva viewed under dark-field illumination, showing the thoracic (T1-T3) and abdominal (A1-A8) denticle bands. *c*, Larvae homozygous for a deficiency or null mutations of *h* exhibit a reduction in the number of ventral denticle bands. Specifically, most of the denticle bands of each even-numbered abdominal segment (A2, A4, A6, A8) are deleted. In addition the naked posterior parts of each odd-numbered segment (A1, A3, A5, A7) are deleted. This frame of deletion extends into the thoracic and gnathal segments; in addition the medial tooth, a derivative of the labrum, is disrupted. The precise limits of the deleted regions are indicated in the left-hand half of the schematic larva shown in *a*. These have been deduced from the study of partial deletions in weaker genotypes (P.W.I. *et al.*, in preparation) and, in the case of the A1/A2 deletion, by using the *Ultrathorax* (*Ubx*) mutation to mark anterior A1 derivatives²³. The deleted region in larvae exhibiting this regular pair-rule phenotype varies in size but is approximately the same width as a segment. It includes the segment boundary, its limits being anterior to the presumed position⁴⁰ of the anterior/posterior compartment boundary in each segment. *d*, Larvae carrying null mutations of *ftz* (*ftz*^{W20}/*ftz*^{9H34})^{7,16} exhibit a phenotype which is the reciprocal of that typical of *h* mutants. Thus the anterior of each odd-numbered and the posterior of each even-numbered abdominal segment is deleted. This deletion frame similarly extends into the thoracic and gnathal segments and is shown schematically in the right-hand half of *a*. Our assessment of the *ftz* phenotype differs in several respects from previously published descriptions^{16,17}. For instance we find the H piece, a derivative of the labial segment, to be present, in contrast to the assertion of Wakimoto *et al.*¹⁶ (but see their Fig. 6d which clearly shows an H piece). We also consider the boundaries of the deletion frame to lie, like those of *h*, anterior to the anterior/posterior compartment boundary. This is supported specifically by three observations: (1) The secondary patch of denticles in T1 which lies posterior to the major denticle band but anterior to the Keilins organs (which mark the anterior/posterior boundary)⁴⁰ is partially deleted in *ftz* larvae. (2) The Keilin's organs posterior to the T3 denticle band are usually deleted. (3) Part of the salivary gland which derives from the anterior compartment of G3 is retained in *ftz* mutants (P.W.I., K.R.H., M. E. Akam and A. Martinez-Arias, in preparation).

has a clearly visible effect within 1 h of the cellular blastoderm stage when the germ band fails to extend fully (data not shown). By the time the parasegmental grooves²² are visible (Fig. 2*a*) the metameric organization is obviously disturbed, the germ band being divided into, at most, only half the normal number of parasegmental units (Fig. 2*b*). At the same time, discrete regions of cell necrosis become evident along the length of the germ band (Fig. 2*c*).

hairy RNA during early embryogenesis

Several different transcripts derive from the *h* gene (ref. 23 and K.R.H., in preparation). During embryogenesis two species can be detected by Northern blot hybridization: an RNA of about 2.1 kilobases (kb), denoted α_L , and, at lower levels, a slightly smaller (~2.0 kb) transcript, α_S . The expression of the *h* α transcripts during early embryogenesis has been analysed by *in situ* hybridization of a 1.7-kb genomic probe to wax-embedded sections. Hybridization to adjacent sections with *ftz* probe allows a direct comparison of the expression of both genes in the same embryos (see Fig. 3).

Both *h* and *ftz* transcripts are first detectable during the beginning of the interphase two cycles before cellularization of the blastoderm (stage 12)²⁴. Whilst *ftz* expression is restricted to a specific region, *h* transcripts are more or less uniformly distributed throughout the egg (Fig. 3*d-f*). Subsequently, two distinct regions of *h* transcript accumulation can be detected. Anteriorly, labelling is restricted to the dorsal half of the embryo in a region between 95% and 85% egg length, whilst a second domain of continuous labelling around the entire circumference of the embryo extends from approximately 75% to 20% egg length. Labelling in this latter domain rapidly becomes discontinuous (Fig. 3*g-i*); by mid-stage 14, prior to the completion of cellularization, *h* transcripts are localized in eight distinct regions along the antero-posterior axis of the embryo (Fig. 3*j-l*). The most anterior of these (designated region 0, see Fig. 4*a*) lies between 95% and 85% egg length, extending over 12-15 nuclei. The next most anterior region (region 1) extends around the entire circumference of the egg, being considerably broader ventrally (6-7 nuclei) than dorsally (3-4 nuclei). The remaining six regions (2-7) also extend around the whole circumference,

Fig. 2 In normal development, formation of the cellular blastoderm is followed almost immediately by the onset of gastrulation. Cells along the ventral midline invaginate to form the presumptive mesoderm and the ventral region of the embryo then begins to extend around the posterior pole. On completion of this process (after about 4.5 h of development at 25 °C) the embryo is folded back on itself with its posterior-most tip located dorsally just posterior to the initial position of the cephalic fold, the 'elongated germ band' stage. After a further 90 min, the first evidence of metamerism is visible⁴². The extended embryo becomes subdivided into 14 regions by superficial grooves in the ectoderm. These regions correspond to parasegments^{22,39}, the posterior compartment⁴¹ of one segment and the anterior compartment of the succeeding segment. **a**, A scanning electron micrograph of a wild-type embryo at the extended germ band stage (after about 6 h of development). Superficial grooves in the ectoderm (indicated by arrows) mark the boundaries between parasegments 1–14^{22,39}; the lobes correspond to the rudimentary gnathal appendages (G1–G3)⁴². The single large anterior-most lobe corresponds to the labrum (L). Within each of parasegments 4–13 is a deep invagination of cells which will form the tracheal system. These correspond to the position of the segment boundaries²². **b**, An embryo homozygous for the null allele¹⁸ *h*^{1.79K} at a similar developmental stage to that shown in **a**. This embryo is divided into only half the normal number of parasegments and possesses a correspondingly reduced number of tracheal pits. **c**, A lateral sagittal 2- μ m section through an embryo similar to that shown in **b**. Clusters of darkly stained dead cells are located in discrete regions along the length of the germ band (arrows). All specimens are oriented dorsal side up, anterior to the left.

and are of similar width (each 3–4 nuclei) and evenly spaced. Together, regions 1–7 extend from 75% to 20% egg length (Fig. 4d). At the same stage as the periodic pattern of *h* expression is fully resolved, transcripts from the pair-rule gene *ftz* are localized in seven stripes in the blastoderm (ref. 15 and

Fig. 3). These stripes are similar in width to those of *h* transcript at the equivalent stage.

Although some *h* transcript can be detected over the nuclei, much of the signal is located in the outer cytoplasm (Fig. 4c). This peripheral location of *h* transcripts in the cortical cytoplasm resembles that of *ftz* transcripts and contrasts with predominant localization of *Ubx* transcripts in the nucleus and inner cytoplasm²⁵.

Almost immediately after cellularization is complete, a transverse invagination of cells occurs one-third of the way from the anterior pole at 65–70% egg length¹⁹ (EL; the anterior pole is at 100% EL). This cephalic fold is the first morphological marker to appear along the antero-posterior axis of the previously uniform cellular blastoderm. The invaginating cells correspond to the primordia of the G1 and G2 segments^{19,26,27}.

At the onset of gastrulation, *h* regions 1 and 2 can be seen to flank the cephalic fold, region 1 being drawn into the anterior margin of the fold, whilst region 2 lies posterior to it (Fig. 4e). At the same stage the most anterior *ftz* region is located at the posterior of the fold (ref. 15 and Fig. 4f). As gastrulation proceeds, the periodically distributed *h* transcript rapidly decays (Fig. 3m–o). By the time the germ band has elongated, there is no evidence of the repeating pattern typical of the blastoderm. Transcript, however, is present in the hindgut and the foregut (Fig. 3p, q).

Domains of *h* and *ftz* RNA localization

To determine more precisely the relationship of the *h* and *ftz* patterns, probes for both transcripts were applied simultaneously to the same section so that the resultant signal represents the sum of the two individual signals (Fig. 5a, c). The two probes were also applied individually to the adjacent sections so that in any given embryo the signal from either *h* or *ftz* RNA alone could be distinguished (Fig. 5b, d). The mixed probes (Fig. 5a) clearly define the anterior dorsal patch of *h* RNA. Ventrally in the region between 75% and 15% EL, eight discrete regions of labelling can be resolved, each separated by a single unlabelled incipient cell. The eight labelled stripes are each about six or seven nuclei wide.

Since both *h* and *ftz* patterns consist of seven regularly spaced stripes, it is probable that the two terminal stripes in the pattern detected by the mixed probes consist of only one species of transcript. The anterior-most stripe in the mixed pattern represents *h* transcript, since *h* region 1 lies in the anterior part of the cephalic fold, whereas the anterior-most *ftz* stripe lies in the posterior part of the fold (see Fig. 4c, d). The posterior-most stripe must therefore be due to *ftz* transcript. Thus, the total domains defined by *h* and *ftz* transcripts are out of register by one metamer unit. In addition, the two patterns are out of phase with one another, though not to such a degree that they define complementary regions of the cellular blastoderm. The central six stripes must represent the addition of the two signals, with the anterior of each broad stripe being due to *ftz* signal and the posterior to *h* signal.

Maternal determinants

Polarity along the dorso-ventral and antero-posterior embryonic axes is established under the influence of maternally derived gene products¹³. The *h*-transcription pattern is asymmetrical along both these axes, implying that its generation requires such maternally acting genes. To test this possibility, *h* expression was analysed in embryos produced by two maternal-effect mutations, *dorsal* (*dl*) and *bicaudal* (*bic*).

Females homozygous for the *dl*¹ mutation produce embryos in which cellular fates are changed such that all regions of the embryo behave as though they were dorsal¹³. In the absence of the *dl*⁺ product, the *h* transcription pattern at stage 14 is altered, being approximately symmetrical along the dorso-ventral axis; this is particularly clearly illustrated at the anterior pole where transcript accumulates both dorsally and ventrally (Fig. 6b).

Homozygous mutant *bic* females produce embryos in which the anterior half is frequently replaced by a mirror-image

posterior^{13,28}. This change is invariably accompanied by a reduction in the total number of segments (see ref. 28 and Fig. 6c). Both these features are reflected in the pattern of *h* transcript distribution in stage 14 embryos derived from *bic* females. Region 0, which characterizes the anterior pole of the embryo, is frequently absent. Fewer regions of transcript accumulation are present (Fig. 6d), and their position differs from wild type.

An analogous effect on *ftz* expression has recently been reported²⁹.

Discussion

Transcription of *hairy* is first detectable during embryogenesis at the syncytial blastoderm stage. The transcripts, which are initially distributed throughout the embryo, become localized periodically along its antero-posterior axis at about the time the

body plan is thought to be established. This localization is presumably intrinsic to the process of segmentation because absence of *h*⁺ activity during embryogenesis causes a similarly periodic pattern of deletions along this axis. These deletions arise following a failure of the subdivision of the early embryo into the appropriate number of metameric units and are associated with localized cell death.

There are eight regions of *h* transcript accumulation in the cellularizing blastoderm, equivalent to the number of regions deleted from the larval cuticle. Superposition of the pattern of hybridization and the blastoderm fate map (Fig. 4d) suggests that these sites correspond broadly to the locations of the primordia of the missing structures. Similarly, *ftz* transcripts are localized in seven regions which correspond approximately to the primordia of structures deleted in *ftz* mutant larvae¹⁵.

Fig. 3 (Left) Comparison of *h* and *ftz* transcription during early embryogenesis. The central panels are bright-field images of sections through successively older embryos. In all cases, anterior is to the left. All sections are sagittal (dorsal side up) except for those in *d-f*. After nine rapid divisions in the yolkly central region of the egg, most nuclei migrate to the peripheral cytoplasm to form the syncytial blastoderm^{24,43}. Here they divide a further four times, before cell membranes begin to grow inwards, isolating each nucleus and forming the cellular blastoderm (stage 14 of Foe and Alberts²⁴). Stages were determined by comparing the density of nuclei along the egg periphery. The pattern of *h* or *ftz* expression in each embryo is revealed by the dark-field images of adjacent sections hybridized with ³⁵S-labelled *h* probe (left) or ³H-labelled *ftz* probe (right) respectively. *a-c*, Stage 10 embryo; no expression of either *h* or *ftz* has been detected at this stage. Exposure, 30 days. *d-f*, Frontal sections of stage 13 embryo. Expression of *h* extends around most of the circumference of the embryo with the possible exception of the posterior polar region. In contrast, *ftz* expression is limited from the outset to a region from between 65% to 15% EL. In both cases the silver grains are most densely localized over the nuclei (n); the intensity of nuclear labelling is not uniform. PC, pole cells. Exposure, 30 days. The three embryos shown in the next nine panels are directly comparable being hybridized under precisely the same conditions. Exposure, 20 days. *g-i*, Early stage 14 embryo. Anteriorly, the *h* transcripts have become restricted to the dorsal surface. The remaining region is becoming discontinuous, with seven regions being apparent dorsally. At the same stage, the *ftz* transcripts are also starting to become localized. By mid-stage 14 (*j-l*), both *h* and *ftz* transcript patterns are well resolved into a series of stripes along the antero-posterior axis. This pattern begins to decay with the onset of gastrulation (*m-o*), the decay appearing more rapid in the case of *h* (compare the signal levels in *m* and *o* with the neighbouring stage 14 blastoderm in the top left corner). Note, however, that the anterior dorsal patch of *h* transcript remains prominent at this stage. By the completion of germ-band extension the periodic pattern of both transcripts has decayed. Expression of *h* is now detectable in the developing hindgut and foregut (the proctodaeal (P) and stomodaeal (ST) invaginations respectively) but not in the posterior midgut (pmg), and persists in this region throughout the elongated germ-band stage. *p, q* Show such an embryo just prior to the onset of germ-band shortening. Exposure, 11 days.

Methods. Eggs were collected from rapidly laying fly populations on yeast/agar medium and incubated at 25 °C until the desired developmental stage had been reached. Prior to fixing, the chorion was removed by incubation in 14% sodium hypochlorite. Fixation was in 4% paraformaldehyde in phosphate-buffered saline. The embryos were first pre-fixed by the phase partition method⁴⁴; vitelline membranes were then removed by the method of Mitchison and Sedat⁴⁵. After rehydration, embryos were fixed for a further 15 min, dehydrated and embedded in paraffin wax. Sections (6 µm) were cut and mounted on glass microscope slides, coated with poly-D-lysine. After removal of the wax with xylene, sections were rehydrated and prepared for hybridization essentially as described elsewhere^{46,47} except that the slides were additionally treated with 0.25% acetic anhydride in 0.1 M triethanolamine pH 8.0 for 10 min at room temperature before the final dehydration⁴⁸. DNA templates for transcription were subcloned into pSP64 or pSP65⁴⁹ and ³H- or ³⁵S-labelled RNA synthesized in a 20-µl reaction containing 40 mM Tris-HCl pH 8.0, 6.0 mM MgCl₂, 10 mM dithiothreitol, 4 mM spermidine, 100 µg ml⁻¹ bovine serum albumin, 0.1% Triton X-100, 1 U µl⁻¹ RNasin (Amersham), 100 µg ml⁻¹ linearized template DNA, 500 µM ATP and CTP with 100 µM ³H-GTP and NTP (NEN) or 500 µM ATP, GTP and CTP with 10 µM ³⁵S-UTP (NEN) and 0.2 U µl⁻¹ SP6 polymerase (Anglian Biotechnology) incubated at 30 °C for 4 h. These reaction conditions were found to maximize the yield of full-length transcripts (K.R.H., unpublished observations). The reaction was terminated by the addition of DNase I to 5 µg ml⁻¹ followed by incubation at 37 °C for 30 min. Probes were size reduced to an average of 50-100 bases using alkaline hydrolysis at pH 10.4 for 40 min at 60 °C⁵⁰. Final specific activities were 1.1 × 10⁸ d.p.m. µg⁻¹ for the ³H-labelled probes and 1.2 × 10⁷ d.p.m. µg⁻¹ for those labelled with ³⁵S-thiophosphate. The templates have been described previously^{21,51}. These probes were used at a final concentration of ~0.3 ng per µl per kb in 50% formamide, 10% dextran sulphate, 0.3 M NaCl, 10 mM Tris-Cl, 10 mM NaPO₄ pH 6.8, 5 mM EDTA, 1 × Denhardt's, 10 mM dithiothreitol, 1 mg ml⁻¹ transfer RNA⁵⁰. A 20-µl aliquot of this solution was dispensed on each slide and spread over the sections with a siliconized glass coverslip. Slides were sealed in plastic boxes saturated with wash buffer (50% formamide, 0.3 M NaCl, 10 mM Tris-HCl, 10 mM NaPO₄ pH 6.8, 5 mM EDTA, 1 × Denhardt's) and incubated overnight at 50 °C. Coverslips were removed by immersing slides in wash buffer plus 10 mM dithiothreitol (WDTT). Slides were washed in fresh WDTT for 4-5 h at 50 °C and treated with RNase A at 20 µg ml⁻¹ in 0.5 M NaCl, 10 mM Tris-HCl pH 8.0, 1 mM EDTA (NTE) for 30 min at 37 °C⁵⁰. Subsequently, they were washed in NTE for 1 h before a further final overnight incubation in WDTT at 50 °C. After dehydration of the sections, slides were coated with Kodak NTB2 emulsion, dried, stored at 4 °C and developed with Kodak D-19 developer (1:1 dilution) for 2 min at 20 °C after the stated exposure time. Controls using sense-strand hybridizations and treatment of antisense-strand hybridizations with RNase A in low salt (data not shown) indicate that the signals are due to specific hybridization.

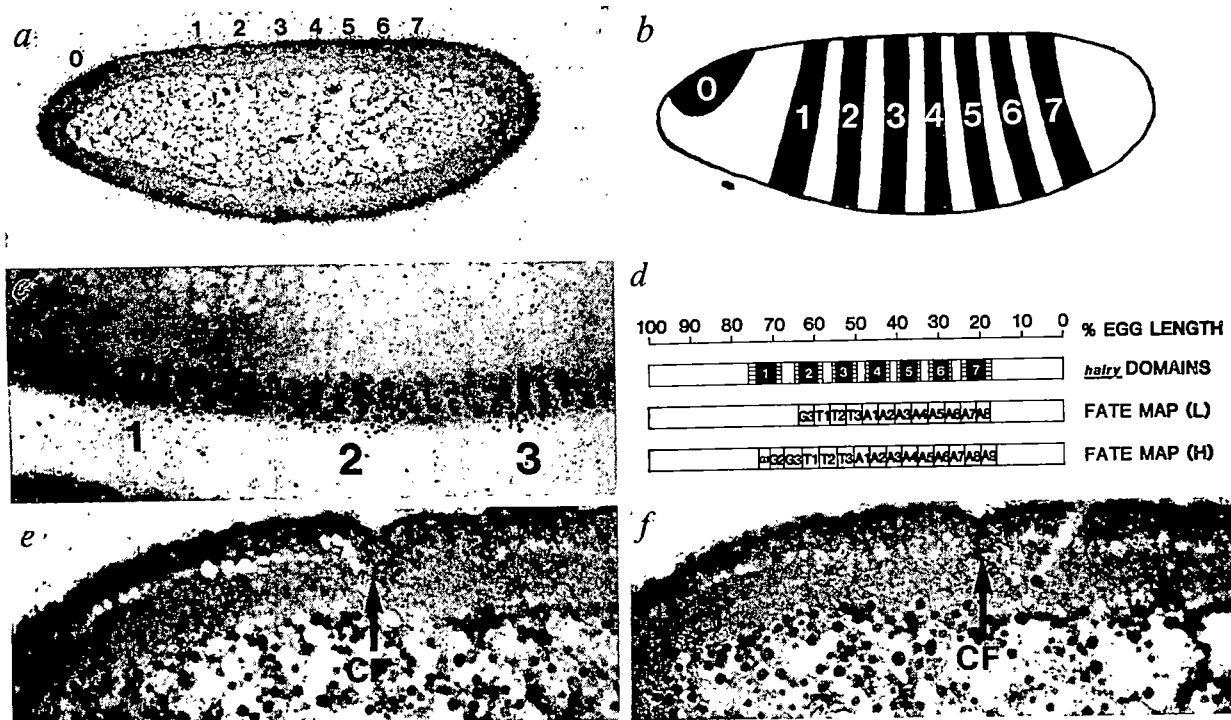

Fig. 4 *a*, Medial sagittal section of a mid-stage 14 blastoderm hybridized with ³⁵S-labelled *h* probe, revealing the eight regions (designated 0-7) of *h* transcript accumulation. *b*, A projection, onto the medial sagittal plane, showing the asymmetry of the pattern of *h* expression. This is based on several partial serial reconstructions. *c*, Detail of the ventral side of a late stage 14 blastoderm hybridized with ³H-labelled *h* probe. Note that domain 1 is broader than domains 2 or 3 which are both 3-4 cells wide. *d*, Projection of the regions of *h* RNA accumulation onto blastoderm fate maps (Lohs-Schardin *et al.*¹⁹ (L) and Hartenstein *et al.*²⁶ (H)). The filled regions show the average localization which involved medial frontal sections of six separate embryos (hatched regions indicate the s.d. of these measurements). Note the approximate correspondence with the primordia for regions deleted in the *h* mutant phenotype (compare with Fig. 1*a*). The two fate maps differ from one another in the exact location of the primordia. Although their estimates for the average size of the primordia (3.9% and 3.65%) are lower than ours (4.2 ± 0.16%), this is due mainly to the broadening of the *h* pattern seen anteriorly. Detailed comparisons with either fate map are not warranted since slightly different assumptions⁵² or level on the dorso-ventral axis¹⁹ were used to construct these maps. *e, f*, *In situ* hybridizations with *h* and *ftz* probes respectively to serial sections of the same early gastrula, illustrating the relationship of the regions of hybridization to the cephalic fold (CF).

One interpretation of these findings is that *h* or *ftz* are autonomously required for the specification of alternating sets of blastoderm cells; mutations in one or other gene would accordingly result in the death of these cells or their descendants. Since the *ftz* and *h* deletion patterns are approximately complementary, a *prima facie* expectation might be that the patterns of expression would show an equivalent relationship. Our results demonstrate, however, that even before cellularization is complete, some incipient cells in the metameric region of the blastoderm express neither gene at significant levels. Such cells could require the expression of one or more of the other pair-rule genes for their specification (see refs 15, 30).

We emphasize, however, that approximate correspondence between the sites of RNA localization and the primordia of structures deleted in the absence of *h* or *ftz* expression does not necessarily imply an autonomous requirement for either gene in these cells. An alternative possibility is that the pair-rule genes are a functionally heterogeneous class, the various genes acting in different ways to establish the metameric pattern.

Although the initiation and subsequent spatial distribution of *h* and *ftz* transcription follow a similar time course, they do exhibit some notable differences. Whereas *h* is initially expressed around most of the egg circumference, expression of *ftz* is restricted from the outset within the presumptive post-oral metameric region of the embryo. Moreover, the disposition of the *h* transcriptional regions appears less uniform than those of *ftz*; regions 0 and 1 are somewhat broader and region 4 slightly weaker than the remaining regions. These differences suggest that the two genes function at different levels.

The striped pattern of both *ftz* and *h* is unstable and has decayed within an hour of the cellular blastoderm stage, the decay of *h* appearing more rapid than that of *ftz*. This latter finding argues against a role for the pair-rule genes in maintaining the segmental pattern. Although it is conceivable that long-lasting protein products of these genes could effect such a function, it is more likely that they act as transient signals which regulate the expression of other genes. A primary candidate for such a gene is *engrailed* (*en*), which is first expressed in a periodic pattern in the cellular blastoderm^{31,32}. In contrast to both *h* and *ftz*, *en* expression continues throughout development in this spatially restricted pattern, reflecting its role in directing the development of the posterior compartment of each segment³³⁻³⁵.

The finding that *h* transcripts accumulate in the anterior region of the embryo throws some light on the question of head segmentation: region 0 includes the location of the labral primordium which is similarly restricted to the dorsal surface of the embryo. Although the lobed appearance of the labrum in the extended germ band (see Fig. 2a) is suggestive of an appendage and hence of its being segmental in origin, such an interpretation has previously been questioned on other morphological grounds³⁶. This would leave only one segment anterior to the mandibular (G1) segment, namely the antennal, the primordium of which maps between the *h* regions 0 and 1. Recently, however, evidence from fate mapping studies^{20,37} together with the analysis of homoeotically transformed larvae³⁸ has suggested the presence of at least two segments anterior to G1. In addition, *in situ* analysis of *engrailed* transcription clearly shows it to be expressed in two regions anterior to G1, one of which is located in the labrum^{3,39}. Taken together, these findings suggest a metameric origin for the labrum, with expression of *h* being required for its establishment.

The significance of the presence of *h* transcripts in the presumptive fore- and hindguts of the extended germ band is at present obscure. We note, however, that *en* is also expressed in these cells at the same stage^{31,32,39}.

The pattern of *h* RNA is not axially symmetrical, the stripes being broader ventrally than dorsally and inclined to the embryonic axis (see Fig. 4b). Presumably this reflects the true shape of the fate map at this stage, since such a pattern is seen well before the beginning of the movements of gastrulation. This contrasts with the assumption of a simple perpendicular

Fig. 5 The spatial relationship of *h* and *ftz* domains. The specific activities of the *h* and *ftz* probes were controlled such that each probe produced a similar signal intensity after a given exposure. Mixtures of the two probes, in equal concentrations, were applied to various sections of wild-type embryos. Adjacent sections of these embryos were hybridized with either the *ftz* or *h* probe alone. **a**, Dark-field image of a sagittal section of a stage 14 embryo hybridized with both *ftz* and *h* probes. Note the dorsal anterior patch of labelling, typical of *h* domain 0. The ventral surface shows a pattern of labelling which is discontinuous, the boundaries between the regions of highest labelling being indicated by the arrows. These subdivide the region into eight. Dorsally, the pattern of labelling is more uniform. Note that the posterior-most *ftz* stripe is always broader than the remainder (see, for example, Fig. 3c). **b**, **c**, **d**, Bright-field images of the ventral regions of successive sections of the embryo shown in **a**, hybridized with *ftz*, *ftz* and *h*, and *h* probes respectively. The labelled region in each case is indicated by black lines. A given cell is taken to be labelled if two or more silver grains are present in its outer cytoplasm. In **c**, arrows indicate cells adjudged to be unlabelled. The size of the labelled domains in **c** is consistent with their being due to the superposition of the individual *h* and *ftz* domains, the *ftz* domain being two nuclei anterior to the *h* domain. Note that the width of the unlabelled regions in the embryo hybridized with *ftz* never exceeds that of the regions labelled with the *h* probe.

relationship between the segmental primordia and the major axis of the blastoderm made in the fate-mapping study of Hartenstein *et al.*²⁶, but confirms the earlier observations of Lohs-Schardin *et al.*¹⁹. This asymmetry reflects a requirement for determinants of both major embryonic axes in the establishment of the *h* pattern. Our results show that in the absence of dorso-ventral polarity the *h* transcription pattern becomes approximately symmetrical. This could imply the existence of a cartesian

Fig. 6 *a*, Dark-field image of section shown in Fig. 4*a*, illustrating the wild-type *h* pattern. *b*, Sagittal section of a mid-stage 14 blastoderm derived from a *dl¹/dl¹* female hybridized with *h* probe. Note the accumulation of *h* transcript both dorsally and ventrally at the anterior pole. *c*, Ventral cuticular pattern of a pharate first-instar larva derived from a homozygous *bic^{M241}* female. The anterior region is replaced by segments of posterior character (A5–A8) in mirror image to the normal posterior. Note the reduction in the overall number of segments. This phenotype is variable but fully penetrant at 18 °C. *d*, Parasagittal section of a sibling of the animal shown in *c* fixed at mid-stage 14 and hybridized with *h* probe. The labelling pattern reveals a reduction in the number of regions of *h* transcript accumulation. This pattern can be interpreted as representing two regions, 6 and 7, in mirror-image symmetry, consistent with the reduction in segment number typical of these embryos (compare with Figs 1*a* and 4*a*). Note also the absence of the anterior dorsal region (0) of transcript accumulation (compared with *a* and *b*).

coordinate system, *h* responding to different antero-posterior values according to position along the dorso-ventral axis. Alternatively, the coordinate system may itself be distorted, reflecting directly the shape of the blastoderm fate map.

We thank Michael Akam and Alfonso Martinez-Arias for advice and stimulating discussions; Jonathan Slack, Jim Smith

and James Vernon for instruction in histology; Gerd Jurgens for making available unpublished data; Janni Nusslein-Volhard and Tom Kaufmann for fly stocks; Matt Scott for the *ftz* clone; Sheena Pinchin, Mimi Broit and Tracy Chaplin for technical assistance; and Rita Harris and Jyotsna Dalal for typing the manuscript.

Are some BL Lac objects artefacts of gravitational lensing?

Jeremiah P. Ostriker & Mario Vietri

Princeton University Observatory, Peyton Hall, Princeton, New Jersey 08544, USA

BL Lac objects are extragalactic, highly variable, polarized sources with significant emission from radio to X-ray wavelengths. However, despite extensive research, their nature and origin remain unclear. We propose here that a significant fraction of the BL Lac objects are optically violently variable quasars (OVVs) whose continuum emission has been greatly amplified, relative to the line emission, by point-like gravitational lenses (either stars or black holes) in intervening galaxies. Several anomalous physical and statistical properties of BL Lacs can be understood on the basis of this model, which is immediately testable on the basis of absorption line studies and by direct imaging.

The class properties of BL Lacs are fairly well-defined, although this may mask an underlying heterogeneity which will retard our comprehension as it did previously with Seyferts, nebulae, or even stars. They are typically point-like (<2 arc s) with the occasional case of extended optical or radio emission perhaps critical to understanding them. In all characteristics so far described, they resemble the OVVs, a class of quasars known for high polarization and variability. They also resemble the OVVs in their optical continuum spectra, where both are steeper than typical quasars, and in their ratio of radio-to-optical where both show higher values. However, they are distinct from the OVVs and from other QSOs in the absence or near-absence of the normal QSO emission lines, even though, during low periods of continuum, emission lines are occasionally seen¹. Statistically, BL Lac objects are uncommon among the brighter extragalactic point sources, constituting perhaps 10% of all objects brighter than $m_B = 16$ (~ 35 objects over the whole sky), and even less common at fainter magnitudes². This is also true of their X-ray properties, where the number-magnitude relation flattens out much earlier than it does for normal QSOs³.

The conventional interpretation is that BL Lac objects are one type of active galactic nuclei. This is supported by the fact that several have been found in relatively small-redshift elliptical galaxies⁴. The variability, high polarization and absence of extended radio structure are attributed to relativistic beaming⁵. While few detailed models have been constructed⁶, the picture is moderately persuasive and is likely to be correct for some subset of the BL Lac objects. There are, however, seriously anomalous features of the observations which are inconsistent with or unexplained by the standard interpretation.

First, there are physical problems. The emitted ionizing continuum would be expected to be absorbed by ambient gas in the elliptical galaxy, with some radiation ultimately degraded to the $H\alpha$ line. Using standard results⁷, we find that if the gas in the elliptical satisfies the inequality $n_e M_{\text{gas}} > 10^{8.5} M_\odot \times \text{atoms cm}^{-3}$, then $H\alpha$ would be detectable in a $m_B = 16$ BL Lac at $z = 0.05$. This is comparable with the amount of gas found in ellipticals, and so, if the gas has not been ejected due to violent nuclear activity, might be expected to be seen in some cases.

Then come the problems with the popular beaming model: it is unlikely that it can, alone, account for the properties of compact radio sources. If the sources whose beams are pointed away from our line-of-sight are identified with radio-quiet quasars, which are otherwise identical to compact sources, why do the compact sources have isotropically emitting haloes, while the extended sources do not? If, on the other hand, extended steep spectrum sources are to be identified with the sources beamed away from us, then the statistics fail, in the sense that there are too few extended QSOs to be consistent with a random-pointing beam. Also, there is at least one extended source

Fig. 1 Number-magnitude relation for OVVs that have been amplified by mini-lensing by at least a factor of 2(a), 10(b) or 100(c), per unit square degree. The OVVs are supposed to have the same luminosity function as the QSOs¹⁶, and to constitute only a fraction $f = 10\%$ of all QSOs.

(3C179) that shows superluminal expansion, and one compact source (4C39.75) that does not.

There are also statistical incongruities. If BL Lacs are nearby objects, a euclidian number-flux relation in the X-ray $N \propto f_X^{-1.5}$ would be expected which is significantly steeper than observed³ for $f_X < 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2}$. This result is not biased by the usual incompleteness of the optical data. Then there is the distribution in distance. Only a small number of BL Lac objects have been examined for absorption line redshifts, with identified systems ranging from $z_{\text{abs}} = 0.424$ (PKS0753+178)⁸ to $z_{\text{abs}} = 1.719$ (0215+15)⁹. This is not unlike the QSO distribution, but it makes anomalous the relatively large number of objects apparently seen in nearby ($z < 0.2$) bright ellipticals. If the typical QSO has $z = 1-1.5$, then the nearest of a sample of 60 should have a $z = 0.16$ (for $\Omega = 1$). This argument is valid for QSOs where the nearest of the hundred brightest objects is 3C273 with $z = 0.158$. But it is highly improbable ($< 10^{-2}$ to find a single object) to have a fraction $\sim 50\%$ of the objects with known redshifts such that $z < 0.2$ as is apparently the case for the BL Lacs. One could avoid this dilemma by imagining the number-luminosity relation to be very steep with many more intrinsically faint than bright objects in comparison with normal quasars, but then the relatively flat number-magnitude relation² becomes even more peculiar. But, if we treat the nearby BL Lacs apparently in galaxies as statistical accidents to avoid these difficulties, we are faced with a wild improbability: one quasar¹⁰ out of 2,000 has been found with its image superimposed on the central regions of a galaxy having $z < 0.2$; so 11 of the 50-odd BL Lacs is extremely unlikely on statistical grounds.

On the basis of this argument, it is attractive to look for an explanation for the phenomenon in which the BL Lacs are at cosmological distances, but the apparently foreground galaxies, whether seen in absorption or in emission, are not there accidentally. We propose that a significant fraction have been gravitationally lensed by point-like objects in the foreground galaxies. Typical optical depths for mini-lensing¹¹ are of the order of 10% for $\Omega_1 = 0.2$, if the haloes of galaxies are made of stellar-like objects. Thus we propose that the OVVs are intrinsically small (or 'beamed') objects, on the basis of the usual variability arguments, and that of the order of 10% of them have been magnified by mini-lenses in intervening galaxies to present us with a BL Lac object. This is made possible by the differing sizes of the continuum-emitting regions ($r \sim 10^{15} \text{ cm}$) and of the line-emitting regions ($r \sim 0.1-1 \text{ pc}$). The line-emitting regions are too large to be lensed by stars, or even black holes up to

the mass of 10^1 – $10^3 M_\odot$ (ref. 12). This model is similar to that proposed by Barnothy and Barnothy¹³, but we are applying it here to only a small subset of QSOs. Normal QSOs are too large, in general, to be affected by mini-lensing.

In recent studies of the effects of lensing on the statistics of QSOs^{14,15}, we found that a class of objects with the postulated properties should be expected to exist on statistical grounds. We have computed the number-magnitude relation for all OVVs that have been brightened by mini-lensing by at least a factor of 2, 10 or 100; the adopted luminosity function is that given by Schmidt and Green¹⁶, truncated at $z=3.5$, and scaled down by a factor of 10, to account roughly for the incidence of OVVs among regular quasars. The results are shown in Fig. 1. Given the prominence of the emission lines of QSOs, it is likely that only objects whose continuum has been brightened by at least a factor of 10 would be classified as BL Lacs. Figure 1 shows the expected apparent magnitude distribution for such objects, assuming a density of point-like lenses equivalent to $\Omega_l=0.2$ (refs 14, 15). The striking feature is the high apparent luminosity at which the counts flatten: $m_B=16$ –18. This agrees qualitatively with the X-ray observations, and explains the negative results of optical searches for faint ($m_B \sim 20$) polarized objects²: both surveys investigated only a small area of sky, where but a handful of objects would be found on the basis of the statistics of regular quasars. On the contrary, we predict that searches would be most successful for large areas of sky and relatively bright limiting magnitudes. Our computation predicts ~ 100 BL Lacs over the whole sky, in agreement with the 50-odd objects discovered in (mostly) the Northern Hemisphere.

The redshift distribution of BL Lacs would be, of course, an insurmountable problem for our model if we accepted that the redshifts attributed to them are their own. But in our model it is natural to suppose that the stellar spectra seen in either emission or absorption are due to lensing galaxies, which are not physically associated with the BL Lacs; the latter are instead at cosmological distances. The redshift distribution expected for BL Lacs, for limiting magnitude of 16, is shown in Fig. 2; it mimics that of QSOs quite closely¹⁶.

There remains an apparent discrepancy for this picture in the comparison between predicted and observed redshift distributions for the lensing galaxies, which lie relatively close to us. Models¹¹ (especially Fig. 2 of ref. 11) show that they should primarily have $z \sim 0.2$ – 0.7 , if they are uniformly distributed in space ($n_l = n_0(1+z)^3$), while we know of at least eight objects¹⁷ which show absorption lines due to stellar spectra, all with $z < 0.2$. But this problem arises also when one considers normal QSOs and lensing by a galaxy, as opposed to mini-lenses; of the six known lensed quasars, one¹⁰ is lensed by a low-redshift galaxy. A tentative explanation for this may be offered (B. Paczynski, personal communication). In accounting for the large splitting and amplification of the known multiple quasars, it was pointed out¹¹ that, if the galaxies are in a cluster with surface mass density Σ approaching the critical surface mass density Σ_{crit} , then the flux is increased by $(1 - \Sigma/\Sigma_{crit})^{-2}$. Similarly, although the analogy is imperfect because the mass distribution in the lensing galaxy will be very grainy, we may expect mini-lensing to be most effective if the stars are located in a galaxy having a mean surface mass density close to the critical density. We find (equation 2.35 of ref. 11) that $\Sigma_{crit} = H_0 c / (4\pi z_l G) = 0.12 h / z_l \text{ g cm}^{-2}$, for $z_l \ll z_{QSO}$, regardless of cosmology. But the mean surface density within the de Vaucouleurs radius is relatively independent of luminosity for elliptical galaxies and is typically of the order of $(1-2)h \text{ g cm}^{-2}$ (ref. 18). Thus, normal ellipticals are near the critical surface mass density for redshifts of the order of $z \sim 0.05$ – 0.1 , which will make mini-lensing in this redshift range more prominent due to the 'amplification bias' already noted¹¹. As the lensing properties approach those for continuum mass distributions as $\Sigma \rightarrow \Sigma_{crit}$, we would expect some BL Lacs in this redshift range to show multiple images, as is the case for the object observed by Huchra *et al.*¹⁰.

Monte Carlo simulations of flux variations due to mini-lensing¹⁹ for 0957+561B show that an average amplification

Fig. 2 Redshift distribution for all OVVs with $m_B \leq 16$, which mini-lensing has amplified by at least a factor of 2(a), 10(b) or 100(c), per unit redshift.

$A \sim 8$ can be obtained for a sufficiently small quasar; the time-scale for flux variation is ~ 5 yr for solar mass stars, a value not inconsistent with that of the observed large-amplitude optical fluctuations. Note also that the relatively small amplitude of the fluctuations obtained by Young¹⁹ (a factor of ~ 2) may be due to the large beam size assumed for 0957+561, which is not an OVV. Also, large swings in the polarization vector during outbursts may be due to mini-lensing²⁰: when the optical depth to mini-lensing is $\tau_{ml} \sim 1$, any subregion of the quasar image can be amplified; which region actually is, depends on the very non-local cooperation of all mini-lenses. If the polarization changes intrinsically in the source, the star motions cause differently polarized regions to be amplified at different times, and the polarization vector to swing during outbursts.

We emphasize that mini-lensing is not alternative to beaming, but depends on it, in that mini-lensing can cause some beamed sources (OVVs) to become BL Lacs. In fact, mini-lensing can relieve the statistical problems of the beaming hypothesis. Tests comparing local densities of BL Lacs and of QSOs have concluded¹⁷ that it is difficult to find a class of radio sources which is numerous enough to be consistent with the statistics of a randomly pointing small beam. If our hypothesis is correct, though, the BL Lacs are at cosmological distances, and this implies that the local density of BL Lacs has been overestimated¹⁷.

The last objection to the mini-lenses hypothesis that we consider here is the following: because we assume that mini-lensing can amplify the optical continuum, but not the line-emitting region, the radio continuum ($r \sim 1$ pc) should not be amplified, and OVVs and BL Lacs should have significantly different (by a factor of 10) radio-to-optical ratios. This objection neglects K-corrections, which are necessary in our hypothesis because the BL Lacs are at cosmological distances. The radio continuum is rather flat ($\alpha_r \sim 0$), while the optical continuum is steep ($\alpha_{opt} \sim 2$), so neglect of K-corrections (of order $(1+z)^2 \sim 10$ for cosmological redshifts) can easily mask different radio/optical flux ratios.

Our simple model has several consequences which make it easy to test.

- (1) One should expect to see absorption redshift systems in a significant fraction of BL Lacs, as they lie at cosmological distances, especially in the objects that show absorption due to stellar spectra. In these objects, one expects to have $z_{abs} > z_{gal}$. As it has been argued that most quasars have $z \leq 2$, we also expect this to be the case for BL Lacs, as observed²¹.
- (2) We predict a continuity of properties between BL Lacs and OVVs, mostly in the relative importance of the line and of the

continuum emission. This continuity has been noticed already for several other properties (polarization, fluctuations of flux and polarization and their timescales)²², with the BL Lacs always having the most extreme properties.

(3) The position of the optical continuum source should not be centred on the image of the associated galaxy, where observed. Two examples of this sort^{1,23}, where the distances are 6.5 and 12 arc s, respectively, are known already, whereas if the BL Lac object is in the galaxy, it should always be centrally located. One might also expect a few objects to have multiple images, or the radio source not to coincide with the optical galaxy²⁴.

(4) But if, contrary to our hypothesis, the strong hard spectrum source sits in the core of a nearby elliptical galaxy, one would often expect to see Balmer line emission from the galaxy, while in our model this should not happen, as there is no physical connection between the hard spectrum source and the galaxy.

We thank M. J. Rees, B. Paczynski and E. L. Turner for helpful discussions. This work was supported in part by NASA grant NAGW-765.

GB841215, the fastest γ -ray burst?

J. G. Laros*, E. E. Fenimore*, M. M. Fikani*,

Darmstadt, FRG

In the 12 yr since the discovery of γ -ray bursts by Klebesadel *et al.*¹, several hundred of these enigmatic events have been observed and catalogued (see, for example, refs 2–5). Their time histories have exhibited a tremendous diversity: they can have durations of milliseconds or minutes; they may contain one or a dozen individual peaks; and they can be highly impulsive or slowly varying. Possibly the only truly unifying observational property of γ -ray bursts is that, with very few exceptions^{6,7}, the bulk of the energy output seems to be in the form of γ -rays. Here we report the detection on 15 December 1984 at 08.25 UT of an extraordinary outburst, qualitatively different in appearance from all previously observed γ -ray bursts. It is described most conveniently as a 'classical' multi-peaked, hard-spectrum burst that has been compressed in time by a factor of 10–100 while simultaneously having its intensity increased by a like factor (thus conserving fluence). Its peak intensity was much higher than any other known γ -ray burst except

for GB790305b, which had an unusually soft spectrum and other unique features that set it apart from 'classical' γ -ray bursts⁸. However, a key point is that if the intensity of GB841215 had been 'normal', its narrow individual spikes would not have been statistically significant with current instrumentation, and the event would have had the appearance of a rather ordinary, short γ -ray burst.

GB841215 was observed by the Los Alamos γ -Burst Detector experiment on the Pioneer Venus Orbiter (PVO)⁹, by the UCB/Los Alamos Solar X-ray/ γ -Ray Burst experiment on the International Cometary Explorer (ICE, previously ISEE 3)¹⁰, and by the medium-energy detectors¹¹ on the European Space Agency's X-ray observatory EXOSAT. Figure 1 shows the time history of GB841215 as obtained by the ICE and PVO experiments. Due to excessively high counting rates induced by this event, EXOSAT suffered a 'crash' of its onboard computer and lost all useful data except for an approximate event onset time. The time bins in Fig. 1 are of unequal length because both the ICE and PVO experiments store data in memories that automatically convert to a 'time-to-spill' mode whenever the rate exceeds 1,365 s⁻¹, that is, the higher rates are derived from the time interval required to accumulate a specific number of counts (16 in Fig. 1a and 32 in Fig. 1b). The statistical properties of such a plot are quite different from those of the familiar Poisson distribution and tend to produce a spikier appearance because the fractional standard deviations do not decrease with increasing rate. The rate changes seen in Fig. 1a, b are significant if they exceed a factor of ~ 2 or ~ 1.4 , respectively. Thus, during the ~ 0.3 -s impulsive phase of the event, at least seven distinct peaks are evident in both parts of Fig. 1, with the sharpest of these having a full width of ≤ 0.005 s in Fig. 1a. No other γ -ray burst has exhibited such rapid multi-peaked structure (hence the word 'fastest' in the title, even though GB790305b may have had a faster rise time). However, it would be unwarranted to conclude that such narrow multiple spikes are rare or unique, because the ability to detect rapid variations is a strong function of intensity—especially in systems with rate-dependent time resolution. If GB841215 had been a factor of 10 or more weaker, it would have had peak rates comparable with other intense bursts, but, its remarkable signature would not have been discernible. Instead, a rather uninspiring 0.3-s event with probable ~ 0.1 -s structure would have been observed. (In fact, other short events observed by PVO have had marginally significant—but never convincing—indications of very fast structure.)

Because of the different energy thresholds of the two experiments (260-keV minimum for the ICE memory data versus 100 keV for PVO), the respective time histories are qualitatively different. In Fig. 1a (higher threshold), the peaks are sharper and the 'valleys' are broader and deeper, relative to b. Evident only in Fig. 1b is the beginning of a weak tail with a softer spectrum that is present for ~ 10 s. The tail does not show any clear modulations, but we have not yet thoroughly investigated this matter. The spectrum of GB841215 is generally very hard, with considerable emission above 1.5 MeV. The total >30 -keV fluence of 4×10^{-4} erg cm⁻² is large, but not exceptional. The peak intensity of $\sim 2.5 \times 10^{-3}$ erg cm⁻² s⁻¹ is exceptional, and has been exceeded only by GB790305b.

The location information for GB841215 is derived from only a three-satellite arrival-time analysis. Accordingly, there are two non-redundantly determined error boxes located approximately symmetrically with respect to the ecliptic plane. (We are still searching for additional data that could lead to a better localization for this event, but the probability of success is not high.) The $\geq 90\%$ confidence error boxes are centred at $(\alpha, \delta)_{1950} = (16\text{ h } 44\text{ min } 48.2\text{ s}, -6^{\circ}42'59'')$ and $(16\text{ h } 17\text{ min } 09.2\text{ s}, -42^{\circ}24'10'')$, or $(L_2, B_2) = (11.2, 23.6)$ and $(338.8, 5.3)$. They are best described as 2° -long segments of an annulus whose axis is located at $(\alpha, \delta)_{1950} = (21\text{ h } 13\text{ min } 19.4\text{ s}, -18^{\circ}10'20'')$ and whose radius is $66^{\circ}13'19'' \pm 4''$. The ends of the two segments are located at $(16\text{ h } 43\text{ min } 37.9\text{ s}, -7^{\circ}40'57'')$, $(16\text{ h } 45\text{ min } 56.3\text{ s}, -5^{\circ}48'03'')$ and $(16\text{ h } 17\text{ min } 29.6\text{ s}, -41^{\circ}23'44'')$, $(16\text{ h } 16\text{ min } 51.7\text{ s}, -43^{\circ}21'33'')$. The total error box area is 33 arc min². Searches

Fig. 1 *a*, ICE time history of GB841215. The energy range is 0.26–2.5 MeV, and the time resolution varies from 0.002 s to 0.012 s. *b*, PVO time history of GB841215. The energy range is 0.1–2.0 MeV, and the time resolution varies from 0.0017 s to 0.012 s.

through various catalogues of γ -ray bursts, pulsars, supernova remnants, flare stars, and high-energy emitters did not result in any source candidates.

We have observed a γ -ray burst with an apparently unique time history. The uniqueness stems from the event's intensity and the rapidity of its temporal structure. However, it is not clear whether the time history is really unique, or whether other events have had similar structure that went undetected due to lack of sufficient event intensity and/or experiment time resolution. If the latter is true, then we must ask if the true 'face' of a γ -ray burst has ever been seen. Are any of our observed γ -ray burst peaks really single peaks? Have any of our measurements (including this one) revealed the underlying fluctuation time scale of a γ -ray burst? Are measured γ -ray burst spectra distorted by pulse pile-up effects? (This could be the case if the photons are emitted preferentially in packets only moderately shorter than the peaks observed in GB841215.) A more detailed discussion of these and other points, as well as a detailed spectral and temporal analysis of this event, will be presented elsewhere.

Change of solar oscillation eigenfrequencies with the solar cycle

Martin F. Woodard* & Robert W. Noyes

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts 02138, USA

*Present address: Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109, USA

Solar acoustic eigenfrequencies depend on the internal structure of the Sun, which may change during the 11-yr cycle of magnetic activity as a result of various effects associated with the solar dynamo. Observations of low-degree acoustic frequencies were made, using the ACRIM instrument on the Solar Maximum Mission (SMM) satellite, in 1980 (near solar maximum) and 1984 (near solar minimum). The analysis of these data, presented here, indicates that the frequencies of $l=0$ and $l=1$ acoustic modes in the 5-min band have decreased from 1980 to 1984, by $\sim 0.42 \mu\text{Hz}$ or 1.3 parts in 10^4 . This finding may have important implications for our understanding of the mechanism of the solar activity cycle.

The ACRIM solar total irradiance data have been described in detail elsewhere¹. For the analysis of 5-min oscillations we use a series of flux estimates obtained at the rate of 1/131.072 s, as defined by the periodic chopping of the solar input to the ACRIM sensor by mechanical shuttering. These data are interrupted by the passage of the SMM into the Earth's shadow about every 96 min and by other, apparently random, data gaps.

Data of sufficient quality for studying the 5-min acoustic (p -mode) frequencies were obtained during 1980 from 18 February to 1 December and in 1984 from 1 May (following the successful repair of SMM) to 31 December. Data obtained in 1985 have not yet been analysed.

Frequencies of low-degree p -modes were derived for both the 1980 and 1984 epochs, by means of discrete Fourier transforms of the data from each epoch. The smoothed periodogram of the 1984 data, for example, is shown in Fig. 1. Figure 2 shows the frequency difference (1980 minus 1984) for the nine strongest oscillation peaks in the ACRIM power spectrum. With one exception, the 1980 frequencies of these modes are higher than their 1984 frequencies. To quantify this trend, we assume that all true frequency differences are identical, and that the error distribution is the same for all measured modes. Then we calculate the mean frequency difference, and estimate its error from the standard deviation of the mean of the points:

$$\Delta\nu = 0.42 \pm 0.14 \mu\text{Hz} \quad (1)$$

The 1980 and 1984 observing windows differ in their details. In particular, data from days 243–273 of 1984 were not available

Fig. 1 Smoothed periodogram of 1984 ACRIM data in the 5-min band, showing solar oscillation modes of degree $l=0, 1$ and 2 , and radial order n in the range ~ 17 – 26 . The unit of power is mean square fractional irradiance variation.

Fig. 2 Measured frequency differences (1980 minus 1984) for individual 5-min solar acoustic modes of degree $l=0$ (○) and $l=1$ (▲), plotted against the frequencies of the modes. The mean and standard deviation of the mean of these nine measurements are indicated by the point labelled $\langle \Delta \nu \rangle$ (equation (1)). The estimated frequency pulling due to the different observing windows (1980 minus 1984) is shown by the point labelled $\langle \Delta \nu_{\text{syn}} \rangle$ (equation (2)).

at the time of the analysis. To test for possible systematic frequency pulling due to the different window functions, we manufactured and analysed time strings sharing properties with the real data. Each synthetic time string is the superposition of variations due to 75 individual oscillation modes plus random variations representing noise. The variation corresponding to an individual mode is patterned after the response of a damped simple harmonic oscillator to a random driving function. The amplitude of the variations representing both those modes seen in the ACRIM data set and random noise was chosen to match the corresponding observed amplitudes in that data set. The amplitude and frequency of the remaining modes, not detected in the ACRIM data, were estimated from velocity oscillation data².

Five independent strings, or runs, of synthetic data were generated. Each run is a separate realization of a statistical process, defined by parameters such as resonant frequencies, linewidths and amplitudes, whose values are the same for all runs. Each randomly generated time series was masked by both the 1980 and the 1984 observing windows and the resulting pair of intermittent data sets from each run was analysed in the same manner as the real data. We therefore obtained five independent estimates of possible frequency shifts due to differences in the window function. From the mean and standard deviation of the mean of five measured shifts, we obtain an estimate of this systematic frequency shift

$$\Delta \nu_{\text{syn}} = 0.06 \pm 0.07 \mu\text{Hz} \quad (2)$$

consistent with no systematic shift. We may obtain a more conservative estimate of the frequency shift of the solar oscillations by subtracting the estimates (1) and (2) and combining their errors quadratically, to give

$$\Delta \nu = 0.36 \pm 0.15 \mu\text{Hz} \quad (3)$$

We have also checked the consistency of the frequencies by comparing portions of the 1984 time series with the whole of the 1980 data. Portion *a* consists of approximately the first 100 days of available 1984 data and portion *b* approximately the final 100 days of that year. The measured frequency shifts (with notation identical to that of equation (1)) are:

$$\Delta \nu_a = 0.43 \pm 0.19 \mu\text{Hz} \quad (4a)$$

$$\Delta \nu_b = 0.36 \pm 0.13 \mu\text{Hz} \quad (4b)$$

Thus the magnitude and sign of the frequency change is consistent between the two portions. We conclude that in 1980, near solar maximum, the low-degree *p*-mode eigenfrequencies were

systematically $\sim 0.4 \mu\text{Hz}$ higher than in 1984 near solar minimum. This result is significant at the 2.5 – 3σ level. We note that a similar change for the most prominent $l=1$ mode of velocity oscillations has been reported³; preliminary analysis indicated a decrease of $0.9 \mu\text{Hz}$ for that mode between 1981 and 1983. In addition, an increase of $1 \mu\text{Hz}$ was suggested for $l=0$ (but not $l=1$) modes from 1980 to 1981.

According to asymptotic theory⁴, the frequency of low-degree acoustic modes of high radial order is proportional, to leading order, to

$$\nu_0 = \left[2 \int_0^R \frac{dr}{c(r)} \right]^{-1}, \quad (5)$$

where $c(r)$ is the adiabatic sound speed and R is the radius of the upper reflection point of the waves and is close to the radius of the photosphere. Thus ν_0 is essentially the reciprocal of the sound travel time across the Sun. The modes used in our analysis (see Fig. 2) have an average frequency of $\sim 3,100 \mu\text{Hz}$. Thus, the frequency change $\Delta \nu$ implies that in 1980, near solar maximum, the sound travel time was shorter by ~ 1.3 parts in 10^4 than in 1984, near solar minimum. A plausible explanation⁵ for this result is that, to an order of magnitude, a similar fractional change in solar radius has occurred, so that the radius is some 10^2 km smaller at solar maximum than at solar minimum. There is other evidence for activity cycle-related changes in the solar radius, from historical meridian circle observations, transits of Mercury and eclipse timings⁶, this evidence also suggests a smaller solar radius at activity maximum, by about the same amount.

It is tempting to associate the observed change in solar *p*-mode eigenfrequencies with a restructuring of the outer convective envelope of the Sun accompanying the activity cycle, for changes in the observed properties of the convective zone have also been reported in association with activity changes. Specifically, both the small-scale granulation⁷ and the larger-scale supergranulation cells⁸ have been found to be significantly smaller at sunspot maximum than at sunspot minimum. Some theoretical studies⁹ have suggested that dynamo generation of magnetic fields deep in the convection zone could lead to a decreased efficiency of convection. This in turn could produce a decrease in the radius of the Sun and a slight increase in *p*-mode eigenfrequencies¹⁰.

Other effects have been suggested which might cause changes in acoustic mode eigenfrequencies correlated with the activity cycle, above and beyond any changes directly coupled to radius changes. Thus Brown¹¹ notes that, in general, turbulent velocities in the convection zone will decrease acoustic mode eigenfrequencies; a decrease in the amplitude of convective turbulence near solar maximum would then lead to an increased frequency at that time, as observed. Bogdan and Zweibel¹² point out that fibril magnetic fields in the upper convection zone, which should be more prevalent near solar activity maximum, would increase the eigenfrequencies, again as is observed. It appears that detailed modelling of a variety of effects may be necessary to explain the observed behaviour; it is hoped that such investigations will produce new insights into the mechanisms of the solar cycle.

We thank T. M. Brown, D. O. Gough, R. Rosner and C. A. Whitney for useful discussions. The reduced ACRIM data were kindly provided by R. C. Willson. This research was supported by NASA contract NAG-5-506.

Ionospheric response to changes in the interplanetary magnetic field observed by EISCAT and AMPTE-UKS

H. Rishbeth*, P. R. Smith†, S. W. H. Cowley†,

B. J. I. Bromage* & S. R. Crothers*

* Rutherford Appleton Laboratory, Chilton, Didcot OX11 0QX, UK

† Blackett Laboratory, Imperial College, London SW7 2BZ, UK

A major question in solar-terrestrial physics concerns the nature of the interaction between the solar wind and the Earth's magnetosphere and ionosphere, and how this depends on the direction of the interplanetary magnetic field (IMF). We report here simultaneous observations of the IMF by the AMPTE-UKS (Active Magnetospheric Particle Tracer Explorers-UK Satellite), and of plasma flow in the high-latitude ionosphere by the EISCAT radar with better time resolution than has been achieved hitherto. We discuss one event in which a sharp southwards turning of the IMF is followed by the onset of rapid ionospheric plasma flow near local noon, demonstrating the close control of ionospheric flows by the IMF. We discuss the causes of the observed 13-min delay, and study the ionospheric heating that accompanies the acceleration.

The AMPTE-UKS¹ has a perigee of 550 km, apogee of 18.7 Earth radii and period of 43.8 h. In October 1984, apogee was near the noon meridian and the satellite was ideally situated to observe the IMF directly upstream of the Earth's magnetosphere and bow shock. The Imperial College magnetometer was operated for periods of up to 10 h during our experiments, and the

data were displayed in real time at the Rutherford Appleton Laboratory (RAL).

For the EISCAT observations we used the UK-Polar programme² to measure F-region plasma velocity at northwesterly ranges of 525(75)975 km from the UHF transmitter at Tromsø. At such ranges, the lines-of-sight to EISCAT's three receiving stations are so nearly parallel that it is necessary to use 'beam-swinging' to measure vector velocities^{3,4}. To reach high magnetic invariant latitudes Λ (71–75°) we pointed the Tromsø antenna at elevation 21.5°, and recorded data alternately at geographical azimuths 332° and 356° in a 5-min cycle. By combining the line-of-sight components measured in the two beam directions, we obtained two-dimensional velocity vectors, which were plotted at RAL shortly after each measurement. This procedure assumes that the plasma velocity does not vary greatly with longitude over distances of the order of 400 km, nor in about 5 min of time, and that the velocity parallel to the geomagnetic field (**B**) is negligible. At high latitudes the plasma velocity is essentially the $\mathbf{E} \times \mathbf{B}$ drift due to a large-scale electric field **E**, and we believe these assumptions do not seriously influence our conclusions.

The coordinated experiments ran for several hours on 29 September, 25 October and 27 October 1984. Here we discuss features of particular interest seen on 27 October, a day of fairly low geomagnetic activity ($\Sigma K_p = 16+$). Figure 1 shows the data sets covering the periods 0600–1510 UT for AMPTE-UKS and 0000–1530 UT for EISCAT. To minimize congestion of the vectors, we plot the EISCAT data in 'electric field' format, in which upwards on the diagram represents a magnetically northward electric field, corresponding to westward plasma drift velocity.

In high latitudes, the ionospheric plasma convection usually has a twin-cell pattern, consisting of a day-to-night flow across the polar cap, with return flows outside the polar cap on both dawn and dusk sides^{3–7}. Because EISCAT cannot normally

Fig. 1 Interplanetary magnetic field and ionospheric plasma drift velocity on 27 October 1984. Data from the Imperial College magnetometer on the AMPTE-UKS spacecraft are plotted as 1-min averages of the Cartesian components B_x , B_y , B_z in the GSM system (in which x points towards the Sun, and the x - z plane contains the geomagnetic dipole vector). Plasma velocity vectors measured by EISCAT are plotted with westward drift (corresponding to northward electric field) pointing upwards, northward drift to the right. In the EISCAT field of view, magnetic local time is approximately 2 h ahead of UT.

Fig. 2 Data for 1030–1150 UT on 27 October 1984, showing 5-s averages of the B_z component of the interplanetary magnetic field measured by AMPTE–UKS; and ionospheric plasma drift velocity, ion temperature and electron temperature measured by EISCAT at 750 km range, 311 km height, invariant latitude 72.6° (\times , Geographical azimuth 332° ; \circ , azimuth 356°). The 40-s oscillations in B_z between 1049 and 1059 UT are probably 'upstream waves' associated with ions reflected from the bow shock¹⁴. According to a recent recalibration, the values of B_z shown in this figure should be reduced by 1 nT.

observe the polar cap by day, our measurements mostly show the return flows, eastward in the morning and westward in the evening. Depending on solar–geophysical conditions, the reversals between eastward and westward flow may occur some hours away from noon and midnight.

From 2350 UT we see predominantly fast eastward plasma flow ($1\text{--}2\text{ km s}^{-1}$), associated with the dawn side of the convection pattern. Between 0230 and 0310 UT this fast-flowing region recedes across the field of view, the poleward speed of the boundary being $\sim 150\text{ m s}^{-1}$ which could be produced by the Earth's rotation beneath a fixed flow pattern. There follow several hours of quieter flow ($0.3\text{--}1\text{ km s}^{-1}$), during which the morning east-to-west reversal of plasma velocity occurs at around 0600 UT. From 0600 the IMF northward component (B_z) fluctuates about zero, becoming positive after 0800 UT.

At 1107 UT the IMF suddenly turns southwards and B_z is mainly negative (0 to -5 nT) for the next 3 h. This change is followed at 1120 UT by a sudden acceleration of the ionospheric plasma flow which we judge to be simultaneous (to within $\pm 1\text{ min}$) over the whole radar field of view. The coherence of the data suggests that the effect is temporal, the plasma being accelerated in $< 5\text{ min}$ to speeds of $\sim 1\text{ km s}^{-1}$ over a range of at least 3° in Λ . In principle, the rapid flow could have started earlier in the auroral oval (probably at $\Lambda \sim 76^\circ$ in quiet conditions⁸) and expanded across the field of view, but that seems unlikely. It would require an equatorward boundary motion of at least 3 km s^{-1} , 10 times what is typically observed⁹. Similar plasma accelerations have been observed by the Sondrestrom radar¹⁰, but with a coarser time resolution of $\sim 25\text{ min}$.

It is reasonable to suppose the southward IMF turning and the acceleration of ionospheric plasma are related, through processes that involve field-line reconnection at the dayside magnetopause. If so, roughly half the observed 13-min delay can be attributed to propagation from the satellite to the ground,

as follows: (1) Travel-time of IMF disturbance from AMPTE–UKS to the subsolar magnetopause: $4 \pm 1\text{ min}$; (2) propagation time of Alfvén waves from the subsolar magnetopause to the cusp ionosphere: $2 \pm 1\text{ min}$.

The other half could be due to three factors. First, the onset of reconnection might be delayed after the arrival of southward-pointing field at the magnetopause, although we do not know why that should happen. Second, several Alfvén transits may well be required to communicate to the ionosphere the full stress imposed by reconnection¹¹. Third, up to 3 min extra delay would occur if (as mentioned above, but considered unlikely) the rapid flow is initiated by an expansion of the auroral oval, instead of being transmitted through the ionosphere in $\sim 1\text{ s}$ at the Alfvén speed. We note that a similar unexplained delay of about 10 min has been found between changes of the IMF B_z and changes of the DP2 current system, as measured by ground-based magnetometers¹². DP2 is the magnetic disturbance associated with the twin-cell plasma convection pattern, which we measure in a more direct way using the radar.

The increase of plasma drift velocity is accompanied by a rise of 400 K in ion temperature between 1120 and 1130 UT (Fig. 2), which we attribute to ion–neutral frictional heating. On the timescale we are considering, the difference between ion and neutral gas temperatures, T_i and T_n , is given approximately by

$$(V_i - U)^2 = (3R/M)(T_i - T_n) \approx 1,300(T_i - T_n) \quad (1)$$

(see ref. 13), where V_i is the plasma drift velocity, U the neutral-air velocity, R the gas constant and M the mean molecular mass of the air (taken as 19 AMU). Assuming that initially $U \approx V_i \approx 200\text{ m s}^{-1}$ and that $T_i \approx T_n$, as seems reasonable, the observed temperature rise of 400 K requires $|V_i - U| \sim 700\text{ m s}^{-1}$, well within our observations. The ion temperature subsequently decreases, presumably because $(V_i - U)$ decays as the neutral air is accelerated by collisions with the drifting ions.

To summarize, we have observed a southward turning of the IMF, followed 13 min later by acceleration of ionospheric plasma. We believe this event demonstrates the connection between ionospheric plasma flows and the IMF direction, although the observed delay is some minutes more than expected on the basis of simple propagation from the satellite to the ground. The ionospheric temperature data support our interpretation. This event is the best isolated southward turning that we observed. We shall discuss elsewhere other, less clear-cut changes of IMF in our data, and we think that the ionospheric response may depend on factors such as local time. We stress the importance of making simultaneous IMF and ionospheric observations with good spatial and temporal resolution.

We thank the director and staff of EISCAT for help, Dr D. J. Southwood for the provision of AMPTE–UKS magnetometer data and Dr W. A. C. Mier-Jedrzejowicz for aid in magnetometer data processing. EISCAT is supported by the British SERC, French CNRS, West German MPG, Norwegian NAVF, Swedish NFR and Finnish SA. AMPTE is a collaborative project of NASA (USA), DFVLR and MPG of West Germany and SERC of the UK. P.R.S. is supported by an SERC grant.

Geomagnetic secular variation in Sicily and revised ages of historic lavas from Mount Etna

J. C. Tanguy, I. Bucur & J. F. C. Thompson

Laboratoire de Géomagnétisme, Université de Paris 6 et CNRS,
94107 Saint Maur des Fossés Cedex, France

The variation of geomagnetic field direction in Sicily during the past 700 yr has tentatively been determined using lavas of known date from Mount Etna¹. Additional palaeomagnetic studies on several hundred volcanic samples, combined with archaeomagnetic investigations carried out on Norman buildings, have improved the previous results and permit a reconstruction of the geomagnetic variation curve to about AD 1000. This curve agrees well with those obtained for other European countries²⁻⁶ and may be used as a reference for checking the ages attributed to archaeological structures as well as volcanic products in southern Italy during the past 1,000 yr. The present results cast serious doubts on the true ages of numerous historically dated lavas from Mount Etna, most of which are at least several centuries older than previously believed. The conclusions have implications for the succession of eruptions, effusion rates, magmatic evolution, and so on, and demonstrate the inconsistency of eruptive models based on historical records alone.

The Etnean lavas from major eruptions during the past 400 yr are well known, the most famous being the 1669 flow that buried about 15 villages and part of the town of Catania. Contrary to popular belief, however, older eruptions are far from being accurately described^{7,8}. Between AD 1600 and 1300, the products of only three eruptive periods can be identified with a reasonable degree of confidence: (1) the 1536 and 1537 flows on the south flank⁹⁻¹¹; (2) the 1408 flow north of Pedara village^{11,12}; and (3) the 1329 cone of Monte Rosso near Fleri (east flank), the name of which is cited in two early manuscripts found by Recupero¹². The palaeomagnetic direction given by welded scoriae from Monte Rosso is consistent with that of a lava flow erupted in 1301-02 on the island of Ischia (Gulf of Naples)¹³: because this eruption is the only one that occurred at Ischia in historical times, its products cannot be confused with others. For com-

parison with Etnean lavas, the magnetic inclination of the Ischia flow has been corrected to the latitude of Sicily.

The lavas mentioned above have been used to reconstruct the geomagnetic variation curve of field direction (Fig. 1), no reference being made to direct measurements as they only extend back to AD 1890 in Sicily. Other flows of supposedly known age, which are shown with quotation marks in Fig. 1, have also been extensively sampled: their peculiar behaviour will be discussed later.

Detailed results and discussion of the techniques of study (such as the removal of viscous remanent magnetization and alternating field demagnetizations) are reported in refs 1 and 7. Note that Etréan lavas are quite sensitive to parasitic magnetizations acquired during sawing or coring. Therefore, we used only 'big' samples (0.5–2 kg) oriented by the plaster method^{1,2}, with azimuth reference from the Sun shadow. This technique also has the advantage of permitting a much better precision during sampling and measurements. Table 1 summarizes the results obtained after magnetic cleaning from lavas of both reliable and dubious dates. The semi-angle of the 95% confidence cone of the average flow directions ranges from 0.71 to 1.76°, thus giving a precision similar to that of usual archaeomagnetic data.

Figure 1 shows that the points corresponding to all the recent flows (AD 1910 to 1610) reproduce the curve of geomagnetic secular variation known from direct measurements in Paris and London^{2,3}, allowing for difference in latitude. By going further back, there is an increasing number of flows (indicated between quotation marks) whose palaeomagnetic directions are inconsistent with that of the geomagnetic field expected at the respective dates. The eruptions to which these lavas were ascribed are poorly located by the historical data. Sometimes, re-examination of early documents enables us to preclude the dates attributed—later—in the modern literature. For example, the “1595” flow, which corresponds to two petrologically distinct flows⁷—“Gallo Bianco East” and “Gallo Bianco West”—in Fig. 1, is undated in documents published before the middle of the nineteenth century. Furthermore, contemporaneous witnesses pointed out that Etna had been inactive for at least 30 yr before 1603 (refs 11, 14). The “1595” date is only quoted by Sartorius in his *Atlas of Etna*¹⁵, although this author does not mention any eruption for this particular year¹⁶. It would appear that “1595” is a printing error. A full discussion of the problems related to spurious dates attributed to Etnean lavas is given elsewhere^{7,8}.

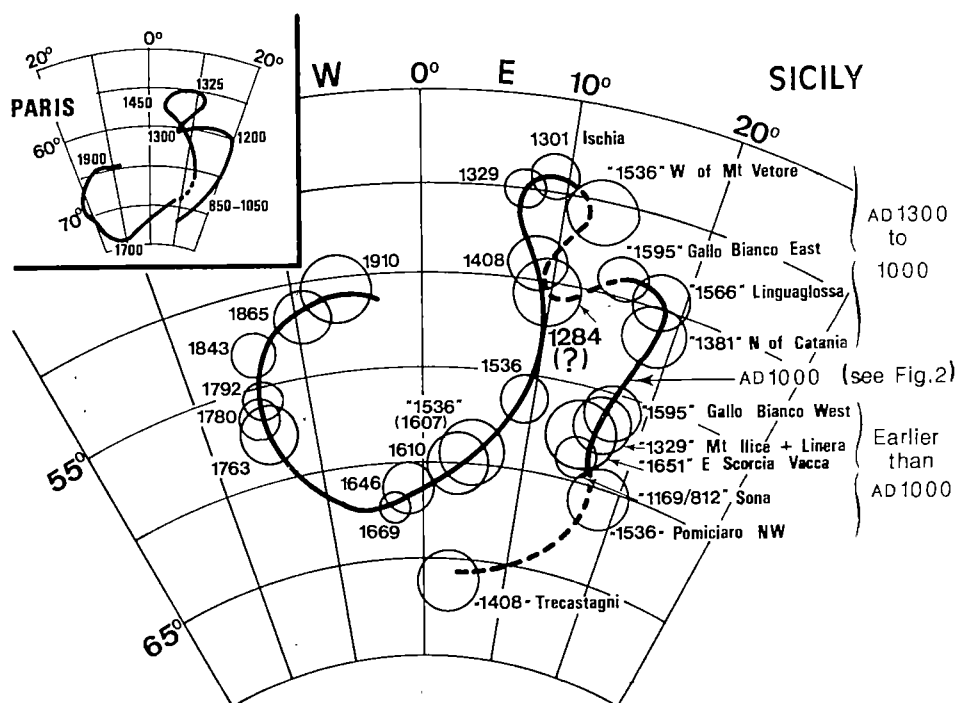

Fig. 1 Geomagnetic variation in Sicily recorded in historically dated Etnean lavas. Ovals indicate the 95% confidence intervals. The dashed lines express uncertainties on the trend of the curve, 1284(?) and "1408" (Trecastagni) being possibly of prehistoric age. Dates in quotation marks are erroneous, although the morphology of the flows indicates a very recent age (see text). Note the general agreement with the archaeomagnetic curve obtained in France (upper left, from refs 2, 17).

Table 1 Palaeomagnetic directions of lava flows or cones of known (a) or presumed (b) ages

a, Volcanic units of known age	N	\bar{I} (deg)	\bar{D} (deg)	α_{95}	k
1669 I	7	61.7	-3.0	0.97	2,963
1669 II+III	7	62.3	-3.6	2.29	535
1669 IV	5	62.7	-3.0	1.62	1,503
1669 V	6	62.6	-2.7	1.35	1,793
1669 VI	5	63.8	-3.3	1.28	2,395
1669 (mean)	30	62.5	-3.3	0.71	1,310
1910	11	50.7	-6.9	1.53	760
1865	18	51.9	-9.5	1.41	583
1843	12	53.2	-14.2	1.12	1,552
1792	23	55.8	-14.2	1.01	837
1780	32	56.7	-14.9	1.04	582
1763	6	57.6	-14.4	1.51	1,437
1646	8	61.3	-1.5	1.25	1,564
1610	10	60.0	3.5	1.61	750
1536, Piano San Leo	21	56.5	8.7	1.04	855
1408, Pedara	12	48.1	7.9	1.67	703
1329, Mt Rosso, Fleri	10	45.1	7.1	1.04	1,824
1301-1302, Ischia	24	44.2	9.0	1.20	566
1284(?) Petrulli-Monacella	18	50.7	9.7	1.52	468
b, Volcanic units of presumed age					
"1651", Scoriavacca	12	57.5	14.7	1.75	581
"1595 I", Gallo Bianco West	16	56.0	17.0	1.44	591
"1595 II", Gallo Bianco East	10	48.9	15.1	1.20	1,351
"1566", Linguaglossa	19	49.7	17.7	1.40	525
"1536 I", West of Mt Vetore	4	45.7	12.6	1.76	1,583
"1536 II", Lower Pomiciaro (north-west)	9	60.7	18.3	1.58	874
"1536 III", Upper Pomiciaro	7	59.4	4.8	1.67	1,172
"1408", Trecastagni North	10	66.1	3.0	1.52	1,060
"1381", Gravina di Catania	12	51.1	18.6	1.41	815
"1329", Mt Illice, Linera	15	56.7	16.4	1.44	731
"1169", Aci Castello	11	57.3	8.2	1.24	1,165
"1169 or 812", Sona (south-west)	8	58.7	14.8	1.04	2,578

N is the number of samples for each eruptive unit (for the 1669 flows, the detail of each site of sampling is shown); α_{95} and k are the Fisher 95% confidence limits and precision parameters, respectively. \bar{I} is the mean inclination and \bar{D} the mean declination.

Thus, most of the lavas believed to have erupted between AD 1651 and 1284 are actually older than this period. The 1284(?) flow itself is problematic; both petrographic and palaeomagnetic evidence⁷ show that it consists of several flows of undoubtedly different ages in the area indicated as a single "1284" lava by Sartorius¹⁵. One of these flows has a palaeodirection that is not inconsistent with the trend of the geomagnetic variation expected for this late thirteenth-century period (compare with Paris and Oxford, Fig. 1 and refs 3, 17). However, its chemical composition and mineralogy are close to those of some prehistoric lavas, and its morphology is less preserved than for any of the historical flows. Thus, there is no objective argument to ascertain whether it could represent the 'true' 1284 lava.

The other flows of presumed age, in contrast, have a well-preserved morphology and petrological characteristics similar to those of well-dated lavas. They probably belong to unrecorded eruptions that occurred during the medieval period, an assumption which is consistent with the results of archaeomagnetic records obtained in other parts of Europe^{2-6,17}. These Etna flows can be used, therefore, to reconstruct the trend of the geomagnetic curve (right-hand side of Fig. 1), although its variation as a function of time cannot be determined, owing to the lack of historical records.

For dating these Middle Age flows of Etna, at least approximately, a preliminary archaeomagnetic study has been carried out on bricks from the walls of six Norman buildings in Sicily (Table 2). Alternating-field cleaning and thermal demagnetization techniques² were applied to the brick samples; the result was an improvement of the 95% confidence intervals, while the mean inclination remained virtually unchanged. The curve of

**Fig. 2** Variation of geomagnetic inclination in Sicily during the past 1,000 yr, from lavas (solid symbols) and bricks (open symbols). The variation of inclination at Paris^{2,17} is shown for comparison.**Table 2** Geomagnetic inclination recorded in bricks from Norman buildings in Sicily

Site	Date (AD)	No. of samples	\bar{I} (deg)	Treatment	Observations
Santi Pietro e Paolo di Agro	≈1000-1060	43	53.5	—	Bricks (church constructed before the Norman period)
		41	53.0 ± 1.4	15 mT	
Santa Maria di Mili	"1092"	25	60.7 ± 2.1	—	Bricks (foundation of church, 1092; possible restoration ~1542)
Santissimo Salvatore di San Marco d'Alunzio	1105	31	51.8 ± 1.7	—	Bricks (monk Gregorio's testament: foundation of church 1105)
Palazzo Reale (Palermo)	1130-1150	47	50.5 ± 1.3	—	Bricks (Pisan Tower windows)
Cefalù	1132-1148	17	53.5 ± 2.1	—	Bricks from the south nave of the church
		17	53.2 ± 1.8	150 °C	
Monreale (Palermo)	1172-1185	17	51.8 ± 2.6	—	Bricks (ornamental material from terrace)
		17	51.2 ± 2.3	140 °C	

geomagnetic inclination obtained (Fig. 2) is very similar to that observed in France (refs 2, 17 and I.B., unpublished data), with the difference of latitude between the two countries taken into account. An unexpected archaeological result concerns the Santa Maria di Mili church: although built in AD 1092, the church has clearly been restored during the sixteenth century, as revealed by the strong magnetic inclination carried by all the bricks sampled.

This new inclination curve for Sicily shows that the supposed Etna flows of "1595" (Gallo Bianco East), "1566" (Linguaglossa) and "1381" (north of Catania) have palaeomagnetic inclinations consistent with eruptions occurring at ~AD 1050-1250. Other flows (lavas from Gallo Bianco West, Mount Illice, Scoriavacca, Sona, Pomiciaro north-west and Trecastagni north) are significantly older, probably between AD 700 and 1000, judging

from the strong increase of inclination recorded at this epoch in Europe^{2-6,17}.

We hope to improve our knowledge of the geomagnetic variation in Sicily by investigating the archaeological structures dated from the Greek civilization to the Roman and Byzantine periods. The resultant curve could be used to check the true age of numerous eruptive products from South Italian volcanoes, as well as archaeological structures of uncertain date.

We thank M. J. Aitken and M. Prévot for advice and criticism. This study is a contribution of the French program of Volcanology (PIRSEV, CNRS-INAG), in the context of a French/Italian cooperation (GNV, CNR).

A dynamic model of the curvature of the Mariana Trench

Albert T. Hsui* & Sarah Youngquist*†

* Department of Geology, and † Physics Department, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801, USA

Oceanic trenches are prominent features of the Earth's surface. They represent the convergent plate boundaries and generally possess convex curvatures towards the subducting plates. Based on this observation, many static geometric models have been proposed for the origin of trench curvatures¹⁻⁶. Unfortunately, many of these models have limited applicability⁷. Alternatively, a dynamic model has been proposed which suggests that trench curvatures are evolved from collisions between aseismic ridges and the trench axis⁸. We have developed a flow model to quantitatively evaluate this dynamic process for the Mariana Trench system. The model is able to yield an excellent fit to the present trench curvature and determine past rotations for back-arc volcanic islands such as Saipan and Guam with surprising accuracy when compared with palaeomagnetic observations.

The Mariana Trench represents the convergent boundary between the East Philippine plate and the subducting Pacific plate. It is bounded to the north by the Marcus-Necker Ridge and to the south by the Caroline Ridge (Fig. 1). Both ridges are classified as aseismic ridges because of their elevated bathymetry and their lack of large seismic activities^{9,10}. These ridges are more buoyant relative to their adjacent oceanic sea floor due to either thermal (for example, higher temperature) or chemical (for example, thicker crust) effects. Because of their stronger buoyant character, they tend to resist subduction⁸. As a result, these aseismic ridges will continue their westward migration while other parts of the ocean floor begin their descent into the mantle. Thus, an initially straight trench will evolve into a convex geometry towards the subducting plate. In this scenario, the overriding plate is assumed to be stationary while the subducting plate is converging. However, the same problem can be formulated in which the subducting plate is chosen to be stationary

Fig. 1 Tectonic setting of the Mariana Trench.

Fig. 2 Observed values of G as a function of y where y is defined in Fig. 3. The solid line represents the mean value for G .

while the overriding plate is flowing over it. As far as the plate boundary geometry is concerned, these two reference coordinates are interchangeable. However, the latter view provides some mathematical simplicities in formulating the problem.

Consider a newtonian viscous fluid with a linear front moving over two stationary point obstacles. The obstacles represent the leading edges of the aseismic ridges as shown in Fig. 1. Since viscosity of geological materials is quite high especially in surface conditions, surface deformation will obey Stokes' flow where inertia forces can be neglected. The governing equation is then given by

$$0 = -\frac{1}{\rho} \frac{dP}{dx} + \nu \frac{d^2 u}{dy^2} \quad (1)$$

where dP/dx is the horizontal pressure gradient arising from stress imbalance within the overriding plate, possibly due to the unboundedness of the trench wall, and it is assumed to be constant; ν is the kinematic viscosity and u is the flow velocity. As the obstacles are stationary, boundary conditions require vanishing velocity at $y=0$ and $y=L$. L is the separation between the obstacles. Consequently, equation (1) can be integrated twice to obtain a velocity profile which in turn can be integrated again with respect to time to yield a curvature profile as given below, where μ is the viscosity of the fluid layer:

$$x = \frac{1}{2\mu} \frac{dP}{dx} (y^2 - Ly)t \quad (2)$$

This equation describes the evolution of a trench curvature according to the model of Vogt *et al.*⁸.

As there are some parameters in the model which are not very well constrained, we shall first attempt to use observed data to determine the acceptable range of values for these parameters. Later, we shall demonstrate that values thus determined are able to fit another set of geophysical data. By doing so, the validity of our model can be established.

Fig. 3 Curvature of the Mariana Trench. The solid line is the observed curvature while the dashed line is the theoretical curvature based on the mean value of G as determined in Fig. 2.

Evolution of the Mariana Trench has been studied by many investigators^{11,13}. The collision between the aseismic ridges and the proto-Mariana trench is set at approximately the middle Miocene time. While some constraints can be established for the timescale, very little can be said about the newtonian viscosity of the surface layer or the pressure gradient across a trench, which are the other two parameters intrinsic to the model. Fortunately, these three parameters can be combined to form a single parameter group [that is, let $1/G = (1/2\mu) (dP/dx)t$]. We shall test if the observed Mariana Trench curvature is able to yield a constant G . Taking the separation between the two aseismic ridges to be $\sim 1,650$ km, the observed values for G are given in Fig. 2. The mean value for this data set is -876.11 km. Based on this mean value, a theoretically predicted trench curvature can be constructed according to equation (2). Comparison of the predicted and observed profiles is given in Fig. 3. Agreement between the model and observation is quite good.

To demonstrate the validity of this model, we shall next examine the relationship between this model and some palaeomagnetic studies behind the Mariana Trench. Application of palaeomagnetic data to study plate rotation has been carried out by many investigators^{11,14-17}. Palaeomagnetic declinations of volcanic rocks of different ages can be measured at the same location. The discordance of palaeomagnetic direction will yield information on the sense and magnitude of rotation for the sampled localities. McCabe¹¹ has compiled some palaeomagnetic data for the southern Mariana Islands. Our model predictions will be compared with these data.

Investigation of a fluid particle rotation within a flow such as the one described previously, requires the theory of finite deformation¹⁸. Geological applications of finite deformation theory have been carried out by Elliot¹⁹ and McKenzie²⁰. In our case, as the flow field is very similar to a steady simple parallel flow, the rate of finite rotation of any fluid particle within the flow can be described by a linear combination of shear strain and fluid vorticity¹⁹, where e is shear strain and ω is vorticity.

$$\dot{\theta} = e + \omega = \frac{du}{dy} = \frac{1}{2\mu} \frac{dP}{dx} (2y - L) \quad (3)$$

Consequently, the finite angle of rotation can be written simply as the time integration of equation (3).

$$\theta = \frac{1}{2\mu} \frac{dP}{dx} (2y - L)t + \theta_0 \quad (4)$$

where θ_0 is the initial angle with respect to the magnetic north prevalent at the time of the collision. Equation (4) can also be derived using a more rigorous approach as described in refs 18, 20. Based on equation (4), finite rotation of the volcanic islands

can be calculated. Note that the time variable t here is not the same as that in equation (2) for trench curvature determination; it is the time that is required for the island to travel from the point when it crossed the line connecting the two obstacles to its present position. Given the flow velocity and the distance, the time duration can be estimated. As a result, rotation of volcanic islands as a function of time can be obtained, and is plotted in Fig. 4; also given are the palaeomagnetic rotation data for Guam and Saipan Islands as compiled by McCabe¹¹. Agreement is surprisingly good.

As indicated in Fig. 3, a parabolic profile is adequate to fit the Mariana Trench. Based on a mean value of -876.11 km for the grouped parameter G , a fit between the theory and the observation can be obtained with a standard deviation of $<5\%$. A closer examination of the comparison indicates that the mismatch is not randomly distributed. The theory over-predicts movement near the centre part of the trench while underestimations occur near the aseismic ridges. One possible reason for this discrepancy may be the existence of a small component of non-newtonian rheology within the overriding plate, since power creep laws will tend to flatten a parabolic profile as evidenced in glacial flow²¹ and in other non-newtonian channel flows²². The non-newtonian contribution appears to be small, however, since the match by a newtonian theory is quite sufficient. Alternatively, the bathymetric trench axis may not represent the actual convergent boundary due to the accumulation of sediments in the accretionary prism²³. Unfortunately, the actual boundary geometry can only be mapped with dense coverage of seismic reflection experiments.

Based on tectonic reconstruction studies, the initial collision between the aseismic ridges and the Mariana Trench has been estimated to have occurred at about the middle Miocene^{11,13}. We thus assign a 15 Myr numerical value for computational purposes. It follows, therefore, that the mean value for $(1/2\mu)/(dP/dx) = 2.4 \times 10^{-21} (\text{m s})^{-1}$. Using this best-fit value, we are able to calculate the velocity of the two volcanic islands (Guam and Saipan), where palaeomagnetic rotation data are available for our model comparison. Table 1 gives the values for velocity and elapsed time for the two volcanic islands. Using

Table 1 Parameter values used for palaeomagnetic rotation calculation

	Guam	Saipan
θ_0 (deg)	-19°	-19°
L (km)	1,650	1,650
Time since collision (Myr)	15	15
x (km)	515.63	556.88
y (km)	1,155.00	948.75
Velocity (km Myr ⁻¹)	43.31	50.88
Time since rotation started (Myr)	11.91	10.95
θ (deg)	-53.26°	-31°

these values, the rotational history for Guam and Saipan can be calculated. Excellent agreement between our model predictions and the observations is clearly demonstrated in Fig. 4. In addition, our model is able to confirm the fact that rotation at Guam is more intense than that at Saipan. It is simply because Guam is closer to the Caroline Ridge. As a result, more vorticity and shearing are expected. Saipan, on the other hand, is closer to the midpoint between the two aseismic ridges where flow is more uniform and with vanishing shear and vorticity. Note that the amount of rotation as determined by our model depends only on the time interval between the present and the time at which the volcanic islands flowed past the leading edges of the aseismic ridges, if the rocks were formed earlier. If rock samples were formed after that time, rotation is calculated based on the time interval between the present and the time at which the rocks were solidified. Consequently, rotation of younger rocks can also be calculated. Unfortunately, data for younger volcanic rocks are not sufficient for a meaningful comparison. Of course, maximum rotation behind the migrating trench will occur in the mid-Miocene volcanics. Rocks with ages older than mid-

Fig. 4 Palaeomagnetic rotation as a function of time for Guam and Saipan islands. Observed rotations (●, ▲) as reported in ref. 11 are also plotted.

Miocene are not expected to show any larger rotation, since the trench is hypothesized to have moved uniformly before the collision with the two aseismic ridges. Because of the excellent agreement between our model and the palaeomagnetic data, the proposed dynamic model for the curvature of the Mariana Trench is believed to be valid. The model is especially attractive because of its ability to explain the differential rotation between Saipan and Guam.

The remaining issue is whether the value of 2.40×10^{-21} chosen for $(1/2\mu)/dP/dx$ is reasonable. To address this question, it is necessary to know the viscosity of the surface layer and the pressure gradient within the overriding plate; neither parameter is very well understood, thus one can only examine the range of possibilities. If the pressure gradient is of the order of a few hundred bars over 1 km, then the viscosity will be about 10^{26} . A pressure difference of a few hundred bars is believed to be reasonable as this is about the strength of surface rocks. Is the required viscosity too low? Although very few studies have been carried out to estimate the viscosity of the surface layer, some laboratory observations have been made in an attempt to provide answers to this question²⁴. Based on Ito's experiment on creep deformation of a granite slab over a 10-yr period²⁴, he found that the deformation of his granite slab can practically be described by a newtonian rheology with a viscosity of $\sim 10^{23}$ Pa s. Thus, our implied value for surface rock rheology is not unreasonable in view of the values derived from Ito's experiments.

We thank Dr Stephen Marshak for many helpful discussions, Dr Peter R. Vogt for his critical review. S.Y. is supported by a graduate fellowship from the AT & T Bell Laboratories.

Palaeobiological and sedimentological implications of fossil concentrations

Susan M. Kidwell

Department of Geophysical Sciences, University of Chicago,
5734 South Ellis Avenue, Chicago, Illinois 60637, USA

Concentrations of fossil hardparts are common features of the stratigraphical record and are preferred collecting sites for most palaeontological data. Nonetheless, most investigations into the nature of the fossil record have analysed the biasing effects of selective hardpart transport and destruction^{1,2} rather than the consequences of the concentration process itself. Genetic classification is discouraged by the diverse origins of skeletal accumulations, which range from predator gastric residues to shelly shoals and biostratigraphically condensed deposits; concentrations can thus form over time intervals of a few minutes to hundreds of thousands of years. I show here that the close association of shell beds with stratigraphical discontinuities in Miocene shallow marine deposits of Maryland^{3,4} provides the basis of a model of skeletal accumulation cast entirely in terms of changes in net sedimentation. This simple sedimentological model is a surprisingly powerful predictor of post-mortem bias and ecological composition of fossil assemblages, suggesting that fossil-rich and fossil-poor strata are qualitatively different, both as repositories of palaeontological information and as settings for biotic interactions. Moreover, the apparent primary importance of rates of sedimentation in skeletal accumulation—despite emphasis usually placed on rates of hardpart input—suggests a new approach to inferring the detailed dynamics of sediment deposition and erosion in the formation of stratigraphical sequences.

Description of the upper and lower contacts of shell (or bone) beds as sharp or gradational has genetic significance because bed contacts not only describe the physical relation of the shell bed to adjacent beds, but also relate the process of hardpart concentration to processes responsible for the accumulation of the surrounding, less fossiliferous sediment. Except for contacts created by bioturbation or diagenesis alone, sharp contacts indicate disjunct shifts in sedimentation and usually record an

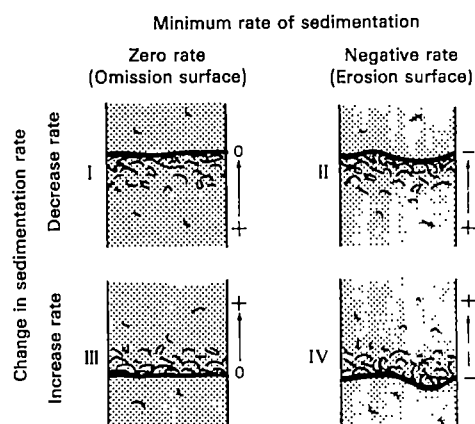

Fig. 1 Field classification of shell beds on the basis of stratigraphical contacts. Type I shell beds grade from less fossiliferous sediment and terminate in a sharp omission surface; type II shell beds also grade upwards with increasing shell-packing density but terminate along an erosion surface; type III shell beds rest on an omission surface and grade upwards into less fossiliferous sediment; and type IV concentrations have erosional basal contacts and grade upwards. Concentrations associated with such surfaces must arise in the context of some change in net sedimentation, since discontinuities indicate conditions of zero (omission) or negative (erosion) net sedimentation, and sediment between discontinuities records positive net sedimentation (deposition).

Table 1 Taphonomic and palaeobiological predictions for four simple patterns of fossil accumulation as modelled in Fig. 1

Shell bed type	Modelled change in sedimentation	Hardpart residence time on seafloor	Hardpart abundance on seafloor	Severity of post-mortem bias					Community composition			Species morphology		
				Physical abrasion & fragmentation	Bio-erosion	Dissolution	Transport addition or removal	Time-averaging	Deep or mobile infauna	Encrusting & boring taxa	Shell gravel taxa	Shell gravel morphs	Variance owing to: Time-averaging	Selective destruction
I	Decrease from + to 0	Increase	Increase	Increase	Increase	Increase	+/- Increase	Increase	Decrease	Increase	Increase	Increase	Increase	+/- Decrease
II	Decrease from + to -	Increase	Increase	Strong increase	Increase	Increase	Increase	Strong increase	Decrease	Increase	Increase	Increase	Strong increase	Decrease
III	Increase from 0 to +	Decrease	Decrease	Decrease	Decrease	Decrease	+/- Decrease	Decrease	Increase	Decrease	Decrease	Decrease	Decrease	+/- Increase
IV	Increase from - to +	Decrease	Decrease	Strong decrease	Decrease	Decrease	Decrease	Strong decrease	Increase	Decrease	Decrease	Decrease	Strong decrease	Increase

Hardpart abundance and hardpart residence time at or near the sea floor are treated as simple functions of rate of sedimentation (hardpart input is assumed to be constant); fossil assemblages sampled from different horizons within any particular shell bed will be characterized by different degrees of post-mortem bias and patterns of biotic response.

episode of erosion or omission (non-deposition)⁵⁻⁷. Hardpart concentrations associated with sharp discontinuities thus must have formed in the context of some change in net sedimentation. These concentrations can be divided into four basic types (Fig. 1), depending on whether hardparts lie on top of or directly underneath the discontinuity surface (as in the "Sohlbanke" and "Dachbanke" of Brinkmann⁸), and whether the surface exhibits scour and truncation features of erosion (negative sedimentation rate) or merely omission (zero net sedimentation rate). As an initial simplifying assumption, hardpart input is assumed to be constant throughout the accumulation period; the model is later shown to hold even after relaxation of this unrealistic assumption.

Type I and type II shell beds (Fig. 1) indicate hardpart accumulation during a slowing down in net sedimentation from high initial rates which exceed hardpart input. Hardpart packing density increases upwards as sedimentation approaches a zero or negative net rate. Type III and type IV beds record an acceleration in sediment accumulation from initially very low rates that foster the concentration of hardparts towards higher positive rates which exceed the background rate of hardpart input. These dynamics of sedimentation have immediate implications for assemblages collected from both fossil-rich and fossil-poor strata.

As rates of sedimentation decrease during the formation of types I and II shell beds, individual hardparts are exposed at the depositional interface for increasingly long periods of time. Assemblages collected from successively higher horizons within the shell bed should thus exhibit a higher frequency and severity of shell damage by abrasion, fragmentation and bio-erosion (Table 1). This trend would be reversed in types III and IV beds. In addition to suffering more pronounced bias owing to selective destruction of hardparts, assemblages that accumulate during the phase of lowest net sedimentation are also more likely to be time-averaged, that is, composite records of a series of populations that occupied the site at different points in time. Time-averaging should be more severe in types II and IV beds than in types I and III beds because of vertical mixing of faunas during erosional reworking. Types II and IV beds are also most likely to be biased by the addition and removal of hardparts through selective transport.

By controlling rates of hardpart burial, net sedimentation also determines the abundance of hardparts in the substratum and thereby influences the physical characteristics of benthic habitats. Ecologically, type I shell beds record the transformation of an initial soft-bottom habitat into an increasingly shelly and thus coarser-textured, firmer and topographically more complex substratum. This change in the physical environment facilitates colonization by borers and encrusters of dead hardparts and by free-living and attached epifauna which prefer or require stable substrata⁹. At the same time, the *in situ* development of a shell gravel inhibits mobile and sedentary burrowers which occupied

the original soft sediment habitat⁹. Types I and II beds should thus exhibit an upward increase in the abundance and diversity of epifaunal species and a concomitant decrease in the numbers of mobile and of especially large or deep-burrowing infauna (Table 1). Assemblages from the most densely fossiliferous parts of the beds will be characterized by ecologically mixed assemblages produced by later shell-gravel taxa occupying the same volume of sediment as earlier soft-bottom taxa; types III and IV beds should exhibit the opposite trend. These shifts in faunal composition should arise regardless of whether the dead hardparts that bring about the change in benthic habitat were produced *in situ* or delivered from allochthonous sources^{9,10}.

Another expected biotic response to variation in shell-packing density is a shift in average shell shape of morphologically plastic taxa—most notably epifauna—which can occupy both soft and shelly bottoms¹⁰. Shell gravel morphs should occur most frequently in assemblages from the most densely packed part of a shell bed (Table 1). Apparent morphometric variance within sampled fossil populations of species should also be greatest there, owing to the time-averaging of the directional shift from soft-bottom and shell gravel morphs and of random non-directional fluctuations in morphology. In types III and IV shell beds, the expected burst of variation followed by a gradual dwindling of variance mimics patterns predicted by some theories of speciation^{11,12}.

The robustness of the sedimentological model is evaluated by relaxing the assumptions, using a series of hypothetical histories of sedimentation and hardpart input (Fig. 2). When hardpart input is allowed to vary (Fig. 2b-e), classification and interpretation of shell beds using the bed contact criterion yields a correct interpretation of sedimentary dynamics in all but one situation: when peaks in hardpart input coincide precisely with maxima in sedimentation (Fig. 2d). This relationship is biologically improbable, because most shelly benthos avoid colonizing settings with high rates of sedimentation. Coincident maxima can occur when hardparts are hydraulically equivalent to enclosing sediments, such as macroinvertebrate shell debris in turbidity current or other high-energy conditions, and microfossil tests in deep-sea environments. These pitfalls can be diagnosed in the field by visual comparison of the hardpart and sediment grain sizes. Figure 2e,f illustrates the results of more complicated patterns of change in sedimentation and hardpart input and more closely mimics real fossiliferous sequences. The robustness of the model for these, as well as for endmember conditions, suggests that the model can be applied successfully to the spectrum of possible combinations of rate changes.

Changes in net sedimentation inferred from bed contacts provide working hypotheses that can be tested by their palaeontological predictions (Table 1) as well as by independent evidence for reduced net sedimentation within the shell bed (glauconite concentration, winnowed sedimentary matrix, physically amalgamated beds). In the Maryland Miocene sequence,

Fig. 2 Synthetic fossiliferous sequences generated from hypothetical patterns of change in sedimentation (solid curve) and hardpart input (dashed curve) provide a test of the robustness of the simple sedimentation model of fossil concentration (Fig. 1). *a*, Condition of constant hardpart input (original model conditions). The sedimentation model correctly interprets the mode of formation of all hardpart concentrations that can be classified as type I, II, III or IV (indicated by ✓). *b*, Constant sedimentation, only hardpart input varies. Concentrations form when hardpart input is relatively high, but none is associated with sharp discontinuity surfaces that permit classification by the model, the model does not lead to erroneous interpretations of the mode of formation (indicated by φ). *c*, Hardpart input varies inversely with sedimentation. Variation in hardpart input simply accentuates concentrations produced by excursions in sedimentation, and thus the model correctly interprets shell beds. *d*, Hardpart input varies directly with sedimentation. When the two rates are identical, fossil abundance does not vary stratigraphically (lower part of synthetic section), but relative concentrations do arise when hardpart input is allowed to exceed sedimentation. The model yields incorrect interpretations (indicated by X) of only those shell beds actually associated with discontinuities. This requires a very particular pattern of sedimentation plus perfect hydraulic equivalence of hardparts with sediment or preferential colonization by macrobenthos during the episode of maximum sedimentation. *e*, Variable net sedimentation, constant background rate of hardpart input with brief positive excursions (for example, mass mortality, allochthonous input). Synthetic pattern of fossil abundance closely mimics real stratigraphical sequences wherein some concentrations are associated with stratigraphical discontinuities, concentrations that can be classified by bed contacts are correctly interpreted by the simple sedimentation model despite random variation in hardpart input. *f*, Complex changes in sedimentation plotted against constant hardpart input. Short-term fluctuations during overall decrease or increase in net sedimentation produce internally complex fossil concentrations; back-to-back monotonic changes produce composite types I-III and II-IV deposits in which both upper and lower contacts are sharp; the model is robust to any pattern of change in sedimentation.

all four large-scale shell beds (Beds 10, 14, 17 and 19 (ref. 13) in Fig. 3a) and most smaller-scale shell concentrations can be classified on the basis of bed contacts as type I, II, III or IV. These exhibit physical evidence of accumulation during intervals of reduced net sedimentation (letter-coded in Fig. 3). Expected palaeontological trends are best developed in the large-scale accumulations, which record skeletal accumulation over prolonged periods of time (estimated at 10^{-3} – 10^{-4} yr each³). As evident in the expanded columnar sections of beds 10 and 17 (Fig. 3b, c), these shell beds exhibit similar vertical sequences: a basal shell hash of largely fragmental infaunal and unbroken epifaunal hardparts; this grades into the main body of the shell bed which contains ecologically mixed and highly amalgamated assemblages of both whole and broken closely packed shells; and an upper interval of closely spaced but discrete shell horizons by which the shell bed grades into less fossiliferous overlying strata. The small-scale types I and IV shell beds which characterize the upper transitional part of these thick, complex type IV shell beds are lags of reworked hardparts from soft-bottom communities, and in some instances have been colonized by epifauna⁹. Directional shifts in bivalve morphology documented within each of the major Miocene shell beds have been interpreted as microevolutionary in origin¹⁴, but might also represent the predicted ecological response to changing substratum characteristics or to concomitant increases in water depth deepening during transgression, or the expected effects of time-averaging. Expected palaeontological trends are thus borne out on several hierarchical scales of skeletal accumulation in this particular setting⁴.

These results with both synthetic and real stratigraphical sections suggest that the model has more than heuristic value. The model should promote palaeobiological comparison of fossil assemblages because it can be used as a testable hypothesis to address a wide variety of skeletal concentrations. Hardpart accumulations can be evaluated regardless of their timescale of

Fig. 3 The Middle Miocene Calvert and Choptank formations (composite section, middle column *a*) include four thick (1–10 m) and laterally extensive (2,500–7,000 km²) shell beds (numbered 10, 14, 17 and 19 in column *a*) and many small-scale concentrations. Most of these are associated with stratigraphical discontinuities—disconformities in the case of the four major shell beds, and scoured or winnowed bedding planes in the case of the minor accumulations (see schematic columns *b* and *c* for expanded scales)—and exhibit independent evidence of concentration during low net rates of sedimentation¹⁵. W, Winnowed matrix; R, hydraulically reoriented specimens; O, overpacked infauna; A, physically amalgamated beds; X, exhumed specimens; B, concentrations of biogenic origin, for example, clumps of shells recording concentration through biological processes, such as gregarious behaviour of the skeletalized fauna or reworking by other organisms.

accumulation (for example, both rapidly formed storm beds and slowly accumulated basal lags on unconformities have type IV structures), physical dimensions, taxonomic composition, proportion of allochthonous hardparts, depositional environment and geological age. Detailed palaeoecological and evolutionary comparisons across environmental gradients or through geological time thus become feasible if a single type of shell bed is sampled throughout. For example, a transect based on erosive washover deposits, swash zone shell laminae, lags produced by channel and shoal migration, inner shelf storm concentrations and shelly proximal turbidites—which are all short-term type IV deposits—should yield assemblages that are ecologically and taphonomically more comparable with one another than to assemblages from short-term types I, II or III deposits. In addition, the absence (or otherwise divergence) of taphonomic trends from those predicted by the model permit the detection of more complex histories and conditions of fossil concentration. Successive horizons within a shell bed might be palaeontologically identical because of: very rapid concentration and burial which sequesters hardparts from destructive processes at the sea floor so that trends never develop; accumulation in environmental conditions (for example anoxia) which exclude potential colonists of dead hardparts; and homogenization by bioturbation. Very rapid formation and burial relative to rates of hardpart destruction and benthic colonization probably explain the less consistent development of expected trends within the small-scale shell beds of the Maryland Miocene, and bioturbation of shell bed contacts may well obscure the sedimentological origin of many others. The complex internal stratigraphies of the major shell beds, on the other hand, record the physical amalgamation of many small-scale concentrations into a single fossil deposit by the superposition of short-term fluctuations on a longer, overall trend in sedimentation rate, such as examined synthetically in Fig. 2f.

If sedimentation is the primary control on skeletal accumulation as indicated by the initial tests reported here, fossil concentrations can yield insights into the basic dynamics (timing and magnitude) of stratigraphical accumulation. The relative frequency of type I, II, III and IV beds should vary among depositional environments owing to differences in sediment supply and hydrodynamics, and suggests a new approach to the mapping and interpretation of sedimentary facies. Qualitatively different patterns of fossil accumulation can also be expected between transgressive and regressive phases of marine deposition, and among basins of different tectonic and latitudinal settings. By referring to fundamental rates and patterns of hardpart input and sedimentation, this approach to modelling has the potential to generate testable hypotheses for a systematic exploration of the nature of the fossil record on several scales.

Sex ratios of an aphid subject to local mate competition with variable maternal condition

Youko Yamaguchi

Entomological Laboratory, College of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606, Japan

Fisher¹ was the first to argue that natural selection would adjust the sex ratio so as to equalize parental investment (PI) in the two sexes, where mating is at random. Hamilton² then showed that female-biased sex ratios would be favoured where male siblings compete for matings, a situation referred to as 'local mate competition' (LMC). In Hamilton's original model and in most subsequent LMC models, the females founding a local breeding population have equal amounts of PI to be allocated between sons and daughters. But in nature, females may differ in total PI and, as a consequence, in fecundity. Here I describe a model for the sex ratios of n co-foundresses, all of which differ in total PI. The model shows that each female with more than a specified minimum amount of PI is selected to make the same absolute investment in sons. All previously published cases of dramatic sex-ratio control occur in haplodiploid species. Here I test my theoretical model against sex-ratio data for an aphid, *Prociphilus oris*, which has a normal diploid genetic system.

Several theorists have considered the sex-ratio strategies of two co-foundresses with different clutch sizes, and they have found that the more fecund female should always produce the more female-biased ratio of investment^{3,4}. 'Double parasitism' of hosts often occurs in natural populations of parasitoid wasps, leading to local competition for mates among the offspring of two females. But in aphids, such LMC often occurs among the offspring of more than two females. Thus for aphids, a more general LMC model is needed.

The model described here embodies the following assumptions. Each local breeding population ('patch') is founded by n inseminated females selected at random from the total population at large. These females differ in their total PI: $P_1 < P_2 < \dots < P_n$, where P_i is the total PI of the i th female. Each female can control her offspring sex ratio, S_i , which is the proportion of P_i invested in sons. Mating occurs at random among the offspring born in the same patch, and all of the female offspring are successfully inseminated. Then the mated female offspring disperse, becoming thoroughly mixed with the rest of the population at large before the next generation's patches are established by taking samples of n females.

Natural selection will favour offspring sex ratios that maximize each mother's inclusive fitness. With a diploid genetic system and autosomal control of the sex ratio, mothers are related equally to their sons and daughters. At the end of the period of parental investment, the expected reproductive success of female offspring (R_f) can be taken to be a constant, equal for all daughters of all mothers. But the reproductive success of a son (R_m) depends directly and immediately on the sex ratios of the mothers in the patch. Thus the inclusive fitness of each mother is a function of her own sex ratio and of the sex ratios of the other mothers, and sex-ratio evolution takes the form of a game in which the best move for each individual depends on what all the others are doing⁵. Below, I derive the optimal sex ratios as the Nash solution or non-cooperative equilibrium of an n -person game, which in this context is the same as an evolutionarily stable strategy⁶.

The inclusive fitness of the i th mother (F_i) in a patch founded by n mothers can be written as⁷

$$F_i = r_d \frac{P_i(1-S_i)}{w_d} R_f + r_s \frac{P_i S_i}{w_s} R_m \quad (i = 1, 2, \dots, n) \quad (1)$$

where S_i = sex ratio of the i th mother; P_i = total PI of the i th mother ($P_1 < P_2 < \dots < P_n$); r_d , r_s = relatedness of a mother to

Fig. 1 Parental investment in sons and daughters, for 176 sexuparae of the aphid *P. oriens*. Total PI in male offspring is indicated on the ordinate ($P_i S_i$), with PI in female offspring shown on the abscissa; $P_i(1-S_i)$. Twenty sexuparae produced sons exclusively; these are represented by the vertical column of points at the left-hand end of the scattergram. Each sexupara produced at least one son. The superimposed rules show the distribution of investments predicted by the theoretical model described in the text.

daughters and sons, respectively; R_f , R_m = reproductive success of a daughter or a son, respectively; w_d , w_s = cost of a daughter or a son, respectively, in units of PI.

Assume that $r_d = r_s$ and that R_f is a constant. It follows that

$$R_m = \frac{\sum_{i=1}^n P_i(1-S_i)/w_d}{\sum_{i=1}^n P_i S_i/w_s} R_f \quad (2)$$

From equations (1) and (2), we have

$$\frac{\partial F_i}{\partial S_i} \propto -1 + \frac{\sum_{i=1}^n P_i(1-S_i)}{\sum_{i=1}^n P_i S_i} - \frac{\sum_{i=1}^n P_i}{(\sum_{i=1}^n P_i S_i)^2} P_i S_i \quad (3)$$

The mean sex ratio is defined as

$$\bar{S} = \frac{\sum_{i=1}^n P_i S_i^*}{\sum_{i=1}^n P_i} \quad (4)$$

where S_i^* is the optimal sex ratio of the i th mother. The Nash equilibrium conditions are

$$(\partial F_i / \partial S_i)_{S_i=S_i^*} \leq 0 \quad \text{if} \quad S_i^* = 0 \quad (5a)$$

$$(\partial F_i / \partial S_i)_{S_i=S_i^*} = 0 \quad \text{if} \quad 0 < S_i^* < 1 \quad (5b)$$

$$(\partial F_i / \partial S_i)_{S_i=S_i^*} \geq 0 \quad \text{if} \quad S_i^* = 1 \quad (5c)$$

By using equation (3), equations (5a) to (5c) can be rewritten as

$$P_i S_i^* \geq \bar{S}(1-2\bar{S}) \sum_{i=1}^n P_i \quad \text{if} \quad S_i^* = 0 \quad (6a)$$

$$P_i S_i^* = \bar{S}(1-2\bar{S}) \sum_{i=1}^n P_i \quad \text{if} \quad 0 < S_i^* < 1 \quad (6b)$$

$$P_i S_i^* \leq \bar{S}(1-2\bar{S}) \sum_{i=1}^n P_i \quad \text{if} \quad S_i^* = 1 \quad (6c)$$

It is convenient to define C as

$$C = \bar{S}(1-2\bar{S}) \sum_{i=1}^n P_i \quad (7)$$

Then equations (6a) to (6c) immediately simplify to

$$0 \geq C \quad \text{if} \quad S_i^* = 0 \quad (8a)$$

$$0 < P_i S_i^* = C \quad \text{if} \quad 0 < S_i^* < 1 \quad (8b)$$

$$0 < P_i \leq C \quad \text{if} \quad S_i^* = 1 \quad (8c)$$

I now consider where each of equations (8a) to (8c) will hold:
Case 1. $S_i^* = 0$. This is impossible. If even one mother produces any sons ($S_i > 0$), then $C > 0$ and equation (8a) is contradicted.

Case 2. $0 < S_i^* < 1$. Equation (8b) can be rearranged to give

$$S_i^* = C/P_i \quad (9)$$

and the condition $S_i^* < 1$ can be rewritten as

$$P_i < C \quad (i = 1, 2, \dots, n) \quad (10)$$

Case 3. $S_i^* = 1$. Equation (8c) implies that

$$P_i \leq C \quad (11)$$

The assumption that all mothers produce $S_i^* = 1$ leads to a contradiction, but a mixture of sex ratios from case 3 ($S_i^* = 1$) and case 2 ($0 < S_i^* < 1$) is possible, because equations (8b) and

(8c) can both be satisfied when $0 < \bar{S} < 0.5$. Thus the Nash equilibrium is

$$S_i^* = C/P_i \quad \text{for} \quad P_i > C \quad (12a)$$

$$S_i^* = 1 \quad \text{for} \quad P_i \leq C \quad (12b)$$

Next, I show that the Nash equilibrium is determined uniquely if the P_i values are given. Substituting equations (12a) and (12b) in equation (4), we obtain

$$\begin{aligned} \bar{S} &= \frac{\sum_{i=1}^n \min(P_i, C)}{\sum_{i=1}^n P_i} \\ &= \left\{ \sum_{i=1}^m P_i + C(n-m) \right\} / \sum_{i=1}^n P_i \end{aligned} \quad (13)$$

where it is assumed that the P_i values are ordered as an increasing series. Equation (13) shows that C is a semi-concave function of \bar{S} , while equation (7) shows that C is a convex function of \bar{S} ($0 < \bar{S} < 0.5$). Thus, there is a unique solution (\bar{S}, C) that satisfies both equations (7) and (13), and m is uniquely determined ($P_m \leq C < P_{m+1}$).

Finally, I calculate \bar{S} . If all mothers produce sex ratios strictly between 0 and 1 (case 2), we have an instance of the 'special case', while if some mothers produce sex ratios of unity (case 3) we have an instance of the 'general case'. The special case represents the general case with $m = 0$.

General case.

$$S_i^* = 1 \quad (i = 1, 2, \dots, m)$$

$$S_i^* = C/P_i \quad (i = m+1, \dots, n) \quad (14)$$

Equation (7) together with equation (13) gives

$$\bar{S} = \frac{1}{4(n-m)} \left\{ (n-m-1) + \sqrt{(n-m-1)^2 + 8(n-m) \frac{\sum_{i=1}^m P_i}{\sum_{i=1}^n P_i}} \right\} \quad (15)$$

C is determined by substituting equation (15) in equation (7).
Special case.

$$S_i^* = C/P_i \quad (i = 1, 2, \dots, n) \quad (16)$$

Combining equation (6b) with equation (4) yields

$$\bar{S} = \frac{1}{2}(n-1)/n \quad (17)$$

Substituting equation (17) in equation (7), we obtain

$$C = \left(\sum_{i=1}^n P_i / n \right) \{ (n-1)/2n \} \quad (18)$$

The equilibrium sex ratios are uniquely determined by the P_i . The optimal sex ratio of the i th mother (S_i^*) is inversely related to her total PI (P_i), if P_i is larger than the constant C ; see equations (14) and (16). This result generalizes the existing sex-ratio models for two foundresses with unequal PI. But the most surprising result is that $C = P_i S_i^*$ —in other words, all mothers with more than C units of total PI are selected to make the same absolute investment in sons, while mothers with less than C units of PI are selected to produce sons exclusively. This is a new result.

If there is little variation in total PI, such that all mothers make some daughters (special case), then the average sex ratio

in each patch is $\bar{S} = \frac{1}{2}(n-1)/n$; see equation (17). This is the same as Hamilton's equilibrium sex ratio for the case in which all females have the same PI. But if some mothers have less than C units of PI (and therefore produce sons exclusively; general case), Hamilton's expectation does not give the exact average patch sex ratio; see equation (15).

At equilibrium, the effect of sibling competition on the inclusive fitness of each mother is the same, because each female produces the same number of sons. This would not be true if, for example, each female produced the same offspring sex ratio, regardless of her total PI.

The aphid *Prociphilus oriens* (Homoptera, Pemphigidae) is a useful species with which to test sex-ratio theories, owing to several features of its biology. It undergoes sexual reproduction once a year, in the autumn. The sexuparae ('mothers', for purposes of testing this model) produce sexuales (males and oviparous females) parthenogenetically. The sexuparae mature and feed on the secondary host, *Abies sachalinensis*. During this period, embryonic sexuales are developing within the sexuparae. When they have finished feeding, the sexuparae moult and fly to the primary host, *Fraxinus mandshurica*. They move around on the primary host for a few hours, looking for places to deposit their offspring; this wandering gives rise to a patchy distribution of sexuparae on the bark of the primary host. Within half a day the sexuparae deposit their offspring and die.

The sexuales stay at their place of birth for a few days, and then become sexually active. The males have very limited powers of movement, and they are sexually active for only about one day. Thus, the sexuales produced by the mothers in a given patch are effectively a breeding population within which there is likely to be significant local mate competition. Mothers appear to have direct control over the sex ratios of their offspring⁸ and their fecundities over a wide range. The observations of mating behaviour of the sexuales showed that they cannot recognize siblings. Thus, *P. oriens* seems to satisfy all of the assumptions of the model.

Sexuales of both sexes complete their development within the bodies of the sexuparae. Lacking mouthparts, they do not feed after birth. Thus the volume of each offspring is an excellent index of its mother's investment in it⁹. The sexuales of *P. oriens* are remarkably dimorphic at birth. The average volume of a male is 0.047 mm³, while that of a female is 0.126 mm³.

Sexuparae were sampled at a site on Hokkaido, the northern island of Japan, in 1982. Sexuparae that flew to a clump of *F. mandshurica* during a period of several hours were caught as they attempted to land on the trees. They were fixed in 75% ethanol and later dissected. For each sexupara I determined the number of her male and female sexuales, and I estimated the volume of each individual sexuelle. The total PI of each sexupara (P_i) was defined as the total volume of her clutch, and her PI ratio (S_i) was then defined as the proportion of the total volume that consisted of sons.

For the sample of 176 sexuparae, the overall numerical sex ratio was almost exactly 0.5 males, while the overall PI ratio was 0.37, which is strongly and significantly female-biased. The difference between the numerical ratio and the PI ratio is caused by the sexual dimorphism of body size mentioned above.

Figure 1 shows the observed PI in sons and daughters for each sexupara. Superimposed on the data are lines illustrating the distribution of PI values predicted by the model, using the value of C calculated from the data. Mothers with less than C mm³ of total PI should invest exclusively in sons (the vertical line), while mothers with over C mm³ should invest C mm³ in sons and the rest in daughters (the horizontal line). The data cluster remarkably well about the theoretical lines.

If females could have been sampled after they had aggregated into local patches, C could have been determined directly from the model, using the observed average value of n and the observed distributions of P_i within patches. Because this was not feasible, I calculated C as the population average of the total volume of males in a clutch. This C value is equivalent to $\bar{C} = \sum_{j=1}^K C_j/K$ ($j=1, 2, \dots, K$, where K is the number of

patches), because the total number of sexuparae sampled would divide into many patches. The good agreement of this C value with the data suggests that the variation of C between the patches is small. The observed mean investment ratio ($\bar{S} = 0.37$) implies that a typical patch contains the offspring of approximately four sexuparae; equations (15) and (17). This inferred value of n is fully consistent with my observations of the behaviour of *P. oriens* at the site from which the sexuparae were obtained. The PI distribution within a patch, however, may vary between patches in nature. Constructing a model which includes the variation of total PI between the patches and also that of the patch size, n , is a job for the future.

I thank Professor R. May for encouraging the publication of this work, and Drs Y. Iwasa, N. Yamamura and Y. Suzuki for many helpful suggestions. Professors E. Kuno and E. L. Charnov read my earlier draft and encouraged the study. I also thank Drs J. Seger and J. W. Stubblefield for their valuable comments.

Recent studies have renewed interest in the role of acetylcholine (ACh) in the cognitive changes associated with ageing and dementia¹⁻⁴. Deficits in cortical choline acetyltransferase (ChAT) in Alzheimer's disease have been consistently demonstrated⁵⁻⁹, while other research has suggested a connection between deterioration of cortical ACh fibres and dementia⁴. However, despite clear biochemical and anatomical evidence for a fall in ACh in dementia¹⁻⁹, results of therapeutic trials with cholinergic agonists, precursors and cholinesterase inhibitors have been inconsistent⁶⁻⁹. Such findings suggest that cortical cholinergic disorders are not wholly a function of simple biochemical change; alterations of impulse flow along cholinergic fibres could well be as debilitating. An important extrinsic source of cortical ACh innervation derives from neurones diffusely located in rat basal forebrain¹⁰⁻¹⁶, denoted the nucleus basalis (NB)^{15,17}. We have now investigated the impulse conduction properties of cortically projecting, putatively cholinergic NB axons in adult and aged rats and have found that conduction latencies from NB to frontal cortex are significantly longer (by 51%) in aged animals. In addition, systematic analysis varying cortical stimulation depth revealed that these longer latencies are due entirely to decreased conduction velocities in the subcortical fibre projections. Indeed, intracortical velocities were virtually identical in the two groups. Our results indicate that ageing occasions a decrease in the temporal fidelity of impulse flow in the cholinergic input to the cortex from the NB, a previously overlooked but potentially important element in cognitive deficits that occur with age.

† Present address: Department of Psychological Medicine, St Bartholomew's Hospital, West Smithfield, London EC1A 7BE, UK.

Fig. 1 Photomicrograph of a coronal section through the basal forebrain of an aged experimental rat (neutral red stain). Pontamine sky blue (spots in NB area, at arrows) was iontophoresed at the locations of two cells driven antidromically from prefrontal cortex. All cells in this study were localized histologically to the NB area in this manner. For calibration, Pontamine spots are 500 μm apart. GP, globus pallidus; IC, internal capsule; CP, caudate putamen.

Six adult (6–8 months) and seven aged (20–29 months) female Sprague-Dawley rats were anaesthetized with chloral hydrate throughout experimental sessions. Aged rats were in good health and remained as viable as adult rats under anaesthesia. A twisted pair of 250- μm -diameter wires, insulated except for bluntly cut tips, was used to stimulate the prefrontal cortex, while a glass micropipette served to record impulses from single NB neurones. The stimulation electrode was placed 0.5 mm below the cortical surface and then raised or lowered in 0.3-mm steps when testing individual cells. Details of stimulation and recording procedures are published elsewhere^{18,19}. Recording sites were marked at the end of successful penetrations by iontophoresing dye from pipette tips. All cells reported here were histologically localized to the NB area (Fig. 1), corresponding to previous anatomical maps of cortically projecting acetylcholinesterase or ChAT-positive neurones^{13,15,20,21}. To control for possible effects of decreased ovarian function with age, half the control adults were ovariectomized 4–6 weeks before experiments. No difference was seen between ovariectomized and intact control rats, and these results were pooled.

Of more than 400 neurones recorded in the vicinity of the NB, 35 in aged animals and 25 in young animals were activated antidromically from the prefrontal cortex. Criteria for antidromicity included constant latency driving, high-frequency activation and collision between spontaneous and driven impulses^{18,19} (Fig. 2). These cells exhibited a variety of rates and patterns of spontaneous activity, resembling the physiological heterogeneity previously found for cortically projecting NB neurones^{18,19}. As also reported previously for young adult male rats^{18,19}, conduction latencies varied widely, yielding values ranging from 1.2 to 16.0 ms in young controls. Despite this heterogeneity, latencies in aged rats were longer overall than in controls, ranging from 2.1 to 27 ms. The mean latency for aged subjects (8.6 ± 0.5 ms) was significantly greater than that for the young group (5.7 ± 0.3 ms), exhibiting a 51% increase ($F = 21.1$, $P < 0.001$).

Nearly every NB neurone, in both young and old rats, could be activated antidromically from the entire depth of the cortex, thus enabling us to compare intracortical and subcortical aspects of the age change in NB axon conduction velocity. Antidromic latencies decreased significantly in a linear fashion overall as the stimulating electrode was lowered to deeper cortical sites ($F = 5.80$, $P < 0.02$) (Fig. 3a). However, although conduction latencies for old rats were consistently longer than for young rats at all cortical depths, slopes of the curves were virtually identical for both groups, yielding estimated intracortical conduction velocities of 0.8 m s^{-1} regardless of age (Fig. 3a). Thus, the entire difference in conduction times between the two groups

Fig. 2 Oscilloscope photographs illustrating collision test for an NB neurone driven from prefrontal cortex in an aged rat. *a*, Stimulation of cortex (arrow) 12 ms after spontaneous spikes (asterisk) elicits driven spikes (filled circle) at 10 ms latency. *b*, Driven spikes are occluded for similar stimuli (arrow) delivered 11 ms after spontaneous spikes (asterisk), indicating collision between spontaneous and driven impulses. Horizontal calibration, 5 ms. Ten superimposed sweeps in each trace.

is accounted for by significantly slower subcortical conduction velocities in aged rats (Fig. 3b).

In contrast to the above conduction changes, several other physiological parameters of NB neurones remained stable in old age. (1) Absolute refractory periods averaged 2.6 ± 0.3 ms in adult controls and 2.4 ± 0.2 ms in aged rats. (2) The number of cells that could be activated antidromically averaged 0.8 ± 0.2 cells per penetration for both age groups. (3) The propensity of axons to exhibit multiple discrete antidromic latencies, previously suggested to reflect intracortical branching¹⁹, was equally evident in both age groups, with averages of 2.8 ± 0.4 and 2.4 ± 0.3 discrete latencies per cell in young and old animals, respectively. (4) Thresholds for antidromic activation were not significantly different between age groups across cortical stimulation depths ($P > 0.1$, Student's *t*-test). (5) There was no apparent difference in the amplitudes of driven impulses in young and aged rats.

Several mechanisms may underlie these age-dependent decreases in NB conduction velocity. (1) Selective loss of larger NB axons, perhaps by shrinkage²², could produce such an effect. However, this process would seem likely also to alter stimulation thresholds, refractory periods and intracortical conduction velocities, none of which showed any significant change with age. Also, the distribution of antidromic latencies revealed an overall shift to longer latencies with age, rather than a loss of one subpopulation. These results, together with the finding that the frequency of encountering driven cells does not change with age, indicate that fibre shrinkage or selective cell loss in aged subjects is unlikely to account for our findings. (2) Similar reasoning argues against the possible mediation of these changes in conduction velocity by altered biophysical properties of the NB axolemma. Although age-associated changes such as increased membrane resistance and viscosity have been reported for other systems^{23,24}, such mechanisms would again be expected to alter not only conduction velocity, but also other electrophysiological characteristics. (3) A third possibility, more consistent with the present data, is demyelination of NB axons. The subcortical conduction velocities obtained for young animals (most of which were $> 3.0 \text{ m s}^{-1}$) indicate that NB axons are normally myelinated subcortically. However, conduction velocities for NB axons within cortex are significantly slower, with mean values (0.8 m s^{-1}) more suggestive of non-myelinated axons^{25,26}. Similar results have been obtained for adult male rats¹⁹. Thus, like mossy fibre afferents to the cerebellar cortex²⁷, NB fibres

Fig. 3 *a*, Mean antidromic conduction latency for NB neurones in adult (filled circles) and aged (open circles) subjects after threshold stimulation at various depths in the prefrontal cortex, as indicated on the abscissa. Note that although conduction latencies are longer at all depths in aged rats, the slopes of the curves are virtually identical, indicating similar conduction times in the two age groups for intracortical impulse flow. In repeated measures analysis of variance, the interaction of age group with cortical depth was nearly zero, indicating that the effect of age was consistent at all cortical depths. The high correlation coefficient (r values) obtained in the regression analysis indicates that these fibres have a strong radial component in their intracortical trajectories, supporting previous anatomical studies^{11,12,36-38}. *b*, Mean conduction velocities for NB cortical afferent fibres in adult (filled bars) and aged (open bars) rats. Conduction velocities within the cortex were calculated for each cell and then averaged, using the difference between the latencies at threshold intensities for 200- and 2,000-μm stimulation depths and a corresponding distance of 1.8 mm. Subcortical conduction speeds (deep cortex to NB) were similarly calculated for each cell using the threshold latency at 2,000 μm and an estimated distance from NB to cortex of 10 mm. Note that conduction velocities within the cortex are virtually identical for adult and aged subjects. Subcortical conduction velocities for young rats (mean \pm s.e.m. = 3.4 ± 0.4 m s⁻¹) are over fourfold higher than those in the cortex, and show a significant decline with ageing (conduction velocity for aged rats = 2.1 ± 0.3 m s⁻¹; $t_{38} = 2.43, P = 0.02$).

may be myelinated until they enter the cortical grey matter¹⁹. Given such a subcortically myelinated projection system, the hypothesis of age-related demyelination is well in accord with all aspects of our data. It explains, for example, why intracortical conduction velocities remain stable with age while subcortical velocities decline markedly. Similarly, demyelination subcortically would not require alteration in refractory periods or thresholds within the cortex. Finally, such a mechanism would leave the relative numbers of fibres and cells intact, a point consistent with our results.

Further research, particularly at ultrastructural levels, will be necessary to test our hypothesis. We note, however, that de-

myelination, whether as a neuropathy in itself or as an effect secondary to axonal pathology, is an established basis for neurological disorders, occurring, for example, in Charcot-Marie-Tooth disease and Friederich's ataxia²⁸.

Ours is not the first report of altered fibre conduction velocity in senescence. Decreased impulse speeds have been found in human peripheral²⁹⁻³¹ and spinal nerves³¹, as well as rodent motoneurons²³ and cerebellar parallel fibres³². However, examples where there is no senescent change in fibre conduction velocity have been reported in both central^{33,34} and peripheral³⁵ nervous systems. Thus, decreased impulse conduction velocity in old age occurs in a restricted set of fibre systems. This selective action may underlie distinct symptoms of the overall ageing syndrome. For example, diminished cerebellar parallel fibre conduction velocity may impair motor coordination³², a common problem in ageing. Similarly, reduced temporal fidelity in the NB cortical afferent system, as described here, may promote cognitive deficiencies characteristic of senescence, and especially pronounced in dementia of the Alzheimer's type.

Although many behavioural studies of ageing have proposed a relationship between cognitive deficits and changes in cholinergic systems⁶⁻⁹, evidence for the latter at the biochemical level is scant. Cortical ChAT decline, for example, occurs consistently in Alzheimer's disease, but not in normal ageing¹⁹. This seldom-addressed paradox may be explained by our findings. Demyelination of cortically projecting cholinergic fibres with age would not necessarily require cholinergic biochemical concomitants, but would nonetheless impair the temporal fidelity of NB-cortical processing, thereby disrupting normal cognitive mechanisms.

If the primary function of the nervous system is to process information by virtue of electrical impulse flow, physiological measurements such as those in the present study may provide a relevant and sensitive index of geriatric cognitive decline.

T lymphocytes possessing helper function produce soluble factors that greatly augment B-cell proliferation and differentiation into antibody-secreting cells¹. In humans the subset of T lymphocytes bearing the T4 surface antigen comprises most of the cells that display helper activity and recognize class II antigens of the major histocompatibility complex (MHC), while the subset bearing the T8 antigen comprises T cells recognizing class I MHC antigens and exhibiting cytotoxic or suppressor function¹⁻³. Monoclonal antibodies to T4 or T8 greatly inhibit the cognitive and effector function of cells with the corresponding phenotype¹⁻⁴. This function/phenotype correlation is not absolute, however, for there are many examples of T8-positive clones that recognize MHC class II antigens and have helper activity, as well as of T4-positive clones with suppressor or cytotoxic function⁵⁻⁹. Recently a family of cell-surface neoantigens, which might be relevant to T-cell function and which are present on activated but not on resting T lymphocytes, has been identified in mouse and humans using monoclonal antibodies¹⁰. Some of these antibodies block the cytolytic activity of alloreactive T-cell clones, suggesting the possible involvement of such molecules in the activation of cytotoxic T-cell clones or in the lytic process itself¹⁰⁻¹³. We now describe a similar late-differentiation antigen (LDA₁) that is expressed by human T lymphocytes only following activation and is recognized by a monoclonal antibody that inhibits the antibody-inducing helper function of T lymphocytes.

Monoclonal antibody anti-LDA₁ was produced by immunizing a BALB/c mouse with an alloreactive T-cell clone (TCC 19) possessing helper function^{14,15}. This hybridoma was originally selected because it reacted with the immunizing T-cell clone (no. 19) but not with peripheral blood T or B lymphocytes or with Epstein-Barr virus-transformed B-lymphoblastoid cell lines from the same donor or from 30 unrelated individuals. Further screening of this antibody on alloresponsive T-cell clones showed that it reacted with all of the 24 helper but with none of the 14 cytotoxic T-cell clones tested. This antibody is of IgG1 subclass as determined by standard immunodiffusion procedures, and was used as an optimally diluted ascitic fluid in most experiments.

Indirect immunofluorescence using an Ortho Spectrum III cytofluorograph^{14,15} showed that LDA₁ is absent on resting T lymphocytes, but appears 1-3 days after the peak of DNA synthesis on a fraction of T lymphoblasts stimulated *in vitro* with plant mitogens, soluble antigens or allogeneic cells. The expression of LDA₁ is dependent on cell proliferation and protein synthesis, as it is prevented by treatment of cells with mitomycin C or emetine-HCl shortly after activation¹⁶. Anti-LDA₁ had no effect on the blastogenic responses of fresh T lymphocytes to plant mitogens, soluble antigens [tetanus toxoid (TT) and purified protein derivative of tuberculin (PPD)] or allogeneic stimulating cells.

Cytofluorometric evaluation of LDA₁ expression on cells grown in primary mixed lymphocyte culture (MLC) showed that 30% LDA₁-positive T blasts are present by day 9, decreasing to <5% by day 14. The fraction of the population expressing LDA₁ was increased, however, to 70% when day-6 MLC-T lymphoblasts were expanded by continuous stimulation with irradiated cells from the sensitizing donor in medium supplemented with interleukin-2.

Fig. 1 Replicate cultures containing 10^7 PBM from an individual with the HLA-DR5,9 phenotype were stimulated in 20-ml tissue culture flasks with an equal number of irradiated PBM from an HLA-DR5,7 donor. Anti-LDA₁ was added at a final dilution of 1:100 to individual culture flasks on day 0, 1, 2, 3, 4 or 5. Control cultures contained no antibody. Ten days after the initiation of the primary cultures, cells were collected from each flask, centrifuged on a Ficoll gradient for removal of dead cell debris, adjusted to 5×10^4 viable responding cells per Microtest well and challenged in triplicate reactions with HLA-DR7-positive (■) or DR7-negative (□) stimulating cells. Secondary cultures were labelled with ^3H -thymidine for 18 h and collected on day 3 (a) or day 5 (b) following restimulation. Results are expressed as mean c.p.m. $\times 10^3$.

Fig. 2 The NSF-K T-cell line was developed by priming PBM from a DR2 homozygous individual to irradiated PBM from a DR3 homozygous stimulator. Day-6 MLC blasts were propagated for 28 days by weekly stimulation with DR3-positive cells in medium containing 20% interleukin-2. Responding T lymphoblasts (5×10^6 culture) were tested for reactivity to DR3-positive stimulating cells in the absence or presence of anti-LDA₁ (1:100 final dilution). The number of viable cells and the rate of ^3H -thymidine incorporation were determined on days 3-6. ○, c.p.m. $\times 10^3$ per 10^5 T cells grown without antibody; ●, c.p.m. $\times 10^3$ per 10^5 T cells grown with anti-LDA₁; △, number of cells ($\times 10^6$) in medium without antibody; ▲, number of cells ($\times 10^6$) in medium containing anti-LDA₁.

To determine whether the number of LDA₁-positive cells could be increased further, T-cell lines that had been propagated for 1 month *in vitro* and which expressed LDA₁ on 70% of the cells, were sorted into LDA₁-positive and -negative fractions using a fluorescence-activated cell sorter (FACS-I; Becton-Dickinson). Both the positively and negatively selected fractions exhibited $30 \pm 12\%$ LDA₁-positive T lymphoblasts after 48 h, and $60 \pm 15\%$ positive cells 120 h after sorting and expansion in cultures. Similar variations in LDA₁ expression were found on the immunizing TCC 19. This helper line, whose monoclonal origin was confirmed by studying the rearrangement of the T-cell antigen receptor β -chain¹⁷, displayed $40 \pm 18\%$ and $80 \pm 15\%$ LDA₁-positive cells, respectively, at 48 and 120 h following each feeding. This indicates that LDA₁ expression is modified on the surface of the alloactivated T lymphoblasts by which it is synthesized.

When added at the initiation of primary MLC cultures, the anti-LDA₁ antibodies did not significantly inhibit the primary day-5 blastogenic response, nor the generation of cytotoxic T

cells in primary MLC or the lytic activity of such cells as determined in a ^{51}Cr -release assay¹⁵.

Because the expression of LDA_1 is acquired only during late stages of the primary MLC response (day 9), we investigated the effect of anti- LDA_1 on secondary MLC reactions, which are usually tested on day 10. The secondary MLC response or the primed lymphocyte test detects accelerated memory responses displayed by cells that have been primed to a specific class II MHC antigen in primary cultures¹⁸. Non-activated cells from the same cultures do not participate in the secondary MLC response, yet maintain the ability to display primary blastogenic responses to the HLA-D/DR antigens for which they bear specific receptors.

Lymphocytes from a responder bearing the HLA-DR5,9 phenotype were primed in MLC to HLA-DR5, 7 stimulating cells. Anti- LDA_1 was added to individual cultures on day 0, 1, 2, 3, 4 or 5 and the secondary MLC response was tested on day 10 by rechallenging the cultures with stimulating cells. The reaction to specific, HLA-DR7-positive stimulating cells was an accelerated memory response, which peaked at day 3 and declined by day 5. The day-3 response was strongly inhibited when anti- LDA_1 was added to the cultures within the first 24 h of primary stimulation, but not when added later (Fig. 1a). None of the cultures showed accelerated (day 3) memory responses to HLA-DR7-negative stimulating cells. However, they displayed primary-type blastogenic responses to such cells on day 5, as expected for a polyclonal population of T cells that can recognize any allelic variants of (non-self) HLA-D/DR antigens in primary cultures. This primary anti-HLA-DR blastogenic response was not significantly inhibited in cultures grown with anti- LDA_1 (Fig. 1b). It appears, therefore, that anti- LDA_1 inhibits the capacity of primed T cells to respond to the sensitizing antigen, as further suggested by its suppressive effect on alloreactive T-cell lines (Fig. 2). The finding that LDA_1 is expressed by T lymphocytes only after activation may explain the difference between the effect of anti- LDA_1 on primary and secondary MLC.

Table 1 Effect of anti- LDA_1 on T-helper function

Individual	Antibody added	Immunoglobulin (ng ml ⁻¹) in cultures with					
		No antigen		Tetanus toxoid		PWM	
		IgG	IgM	IgG	IgM	IgG	IgM
1	None	120	70	360	460	2,400	2,020
	LDA_1	130	60	130	100	410	140
	MB 40.2	110	120	420	510	2,570	2,100
	L243	120	90	120	100	560	180
2	None	160	40	700	2,240	1,050	1,940
	LDA_1	200	20	50	100	300	110
	MB 40.2	130	140	650	2,300	1,160	2,010
	L243	170	30	110	140	250	100
3	None	180	160	1,100	2,800	2,600	3,460
	LDA_1	150	110	380	630	850	720
	MB 40.2	110	120	1,050	2,700	2,580	3,500
	L243	140	150	250	470	760	680

PBM (1×10^5 per reaction) from three individuals recently sensitized to TT were cultured in a round-bottomed microculture plate at 37 °C in a humidified 5% CO_2 atmosphere in RPMI 1640 medium supplemented with 15% heat-inactivated fetal calf serum (FCS), 200 mM L-glutamine, 25 mM HEPES buffer and 1% penicillin/streptomycin. PWM (Gibco) was added to the cultures to a final concentration of $10 \mu\text{g ml}^{-1}$. TT (Massachusetts Public Health Biological Laboratories) was used at a final dilution of 1:400. Cultures were tested in parallel without antibody, with anti- LDA_1 , with MB 40.2, which is an IgG1 antibody reacting with the responders HLA-B antigens, or with L243, which is of IgG2A subclass and reacts with human Ia. The amount of human IgG and IgM contained in 50- μl aliquots of day-6 culture supernatant was quantitated in round-bottomed polyvinyl trays (Costar) coated with rabbit anti-human IgG or IgM (Dako Accurate Chemicals). Known amounts of human IgG or IgM in the same medium were tested as standards. Triplicate wells were used for each reaction. Following 2 h of incubation, wells were emptied, washed in 1% FCS in phosphate-buffered saline (PBS) and covered with 50 μl of a 1:3,000 or 1:1,000 dilution of peroxidase-conjugated rabbit anti-human IgG or IgM respectively. Trays were incubated for 1 h at room temperature in the dark, then washed five times in 1% FCS/PBS, 2,2-Azino-di-(3-ethylbenzthiazoline) sulphonic acid (50 μl), diluted 1:100 in 0.1 M citrate buffer (pH 4.2) containing 0.03% hydrogen peroxidase, was added to each well. After 30 min of incubation at room temperature in the dark, 50 μl of a 1% solution of SDS was added to stop the reaction. The absorbance at 405 nm was read with an automated photometer (Flow Multiskan).

Fig. 3 SDS-polyacrylamide gel electrophoresis (PAGE) of ^{125}I -labelled membrane proteins of TCC 19 cells. 2×10^7 cells were surface labelled with 1 mCi of Na^{125}I (Amersham) using the lactoperoxidase technique as previously described¹⁴. The labelled cells were washed and lysed in 0.5 ml of 100 mM Tris-HCl, pH 7.4/1 mM phenylmethylsulphonyl fluoride/1 mM EDTA/0.5% Triton X-100. The cell lysate was centrifuged at 40,000g for 30 min and the supernatant was filtered through a 0.2- μm Millipore filter. The filtered supernatant was precleared three times by sequential 1-h incubation at 4 °C with protein A-Sepharose, rabbit anti-mouse IgG-coupled Sepharose and an irrelevant monoclonal antibody coupled to Sepharose. The precleared cell lysate supernatant was incubated for 4 h with specific antibody coupled to Sepharose-4B, following the immunoprecipitation procedure described before¹⁴. Immune precipitates were then processed for SDS-PAGE in the presence (reducing condition) of 5% 2-mercaptoethanol using a 7.5% polyacrylamide gel. Lanes a, f, anti- LDA_1 ; lanes b, e, antibody A3 to a framework determinant of human MHC class II antigen; c, d, antibody NAM 1 to human β_2 -microglobulin.

T cells recognizing class II MHC antigens comprise the population of lymphocytes which produce helper factors required for the differentiation of activated B cells into antibody-producing cells. To determine whether T-helper function is also affected by anti- LDA_1 , we tested its effect on immunoglobulin production in cultures in which peripheral blood mononuclear cells (PMB) had been primed to TT or pokeweed mitogen (PWM). Following PWM stimulation, $30 \pm 5\%$ of PWM T blasts expressed LDA_1 by day 4 and $60 \pm 8\%$ were positive by day 6. The equivalent numbers for TT blasts were 19 ± 6 and 42 ± 7 , respectively. Anti- LDA_1 had a strong inhibitory effect on immunoglobulin production in PBM cultures stimulated with PWM or TT (Table 1). Amounts of human IgG and IgM present in the day-6 supernatant of such cultures were significantly lower than those found in cultures grown without monoclonal antibodies or with monoclonal antibody MB 40.2 (ref. 19), which reacts with HLA-B antigens and was used as an isotype-matched control.

The degree of inhibition produced by anti- LDA_1 was of the same order of magnitude as that produced by monoclonal antibody L243 (ref. 20), which reacts with Ia antigens on B cells, monocytes and activated human T cells. Similarly, anti- LDA_1 was as efficient as L243 in inhibiting the capacity of helper T-cell clones possessing anti-HLA-DR¹⁵ or anti-PPD reactivity²¹ to induce B lymphocytes to produce antibodies (Table 2), but anti- LDA_1 had no effect on antibody production by activated, Epstein-Barr virus-transformed β -lymphoblastoid cell lines. Thus, for example, levels of human IgM produced by 1×10^3 B lymphoblasts from one such line in 24, 48, 72 and 96 h were 62, 114, 226 and 350 ng ml⁻¹ in cultures without antibody and 60, 140, 220 and 380 ng ml⁻¹ in cultures containing anti- LDA_1 . Immunoprecipitation studies of the molecule recognized by anti- LDA_1 were performed using ^{125}I -labelled extracts from the immunizing TCC 19. Two bands of $\sim 116,000$ and $150,000$ relative molecular mass (M_r) were found in reducing and nonreducing conditions (Fig. 3).

Our data indicate that anti- LDA_1 detects a late-differentiation antigen expressed by activated T lymphoblasts and inhibits their

Table 2 Effect of anti-LDA₁ on antibody induction by helper T-cell clones

	Immunoglobulin (ng ml ⁻¹) in cultures containing:					
	No antibody		Anti-LDA ₁		L243	
	IgG	IgM	IgG	IgM	IgG	IgM
Anti-HLA-DR1	164	135	30	19	25	18
Anti-PPD	184	98	42	26	38	15

Alloreactive T-cell clones were tested for helper function by incubating 1×10^4 cloned cells with 5×10^4 stimulator type B cells in RPMI 1640 medium containing FCS, glutamine antibodies and PWM, as described previously¹⁵. PPD-specific T-cell clones (1×10^4 cells per reaction) were incubated with autologous T-lymphocyte-depleted PBM in medium containing PPD. Triplicate cultures with no antibody, with anti-LDA₁ or with L243 were tested in parallel. Supernatants were collected from day-6 cultures and the amount of human IgG and IgM was quantitated by enzyme-linked immunosorbent assay. The amount of IgG and IgM produced by B cells alone was less than 25 ng ml⁻¹ and was subtracted from all values.

capacity to produce or deliver the helper signal(s) required for the differentiation of antibody-producing B cells. The inhibitory effect of this antibody is as strong as that displayed by anti-Ia antibodies which interfere with T-B interaction. LDA₁ may represent a cell-surface protein encoded by a 'helper' function gene or by a T-cell receptor gene (possibly Fc) involved in regulating antibody production.

Isolation of the gene and determination of the relevance of its product in autoimmune conditions, allograft rejection or T-cell malignancies is of obvious interest for the future.

Reconstitution of functional receptor for human interleukin-2 in mouse cells

Masanori Hatakeyama, Seijiro Minamoto, Takashi Uchiyama*, Richard R. Hardy, Gen Yamada & Tadatsugu Taniguchi

Institute for Molecular and Cellular Biology, Osaka University, Suita-shi, Osaka 565, Japan

* Department of Internal Medicine, Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto 606, Japan

Interleukin-2 (IL-2) has a key role in the antigen-specific clonal growth of T lymphocytes, by virtue of its interaction with a specific cell-surface receptor (IL-2R)¹⁻⁴. The growth signal seems to be delivered by IL-2 bound to the high-affinity, but not the low-affinity, receptor^{5,6}. Genes encoding IL-2 (refs 7-13) and its receptor (that is, Tac-antigen)¹⁴⁻¹⁷ have been cloned and analysed in detail. We have now achieved cell-type-specific reconstitution of the high-affinity human IL-2R by expressing the complementary DNA

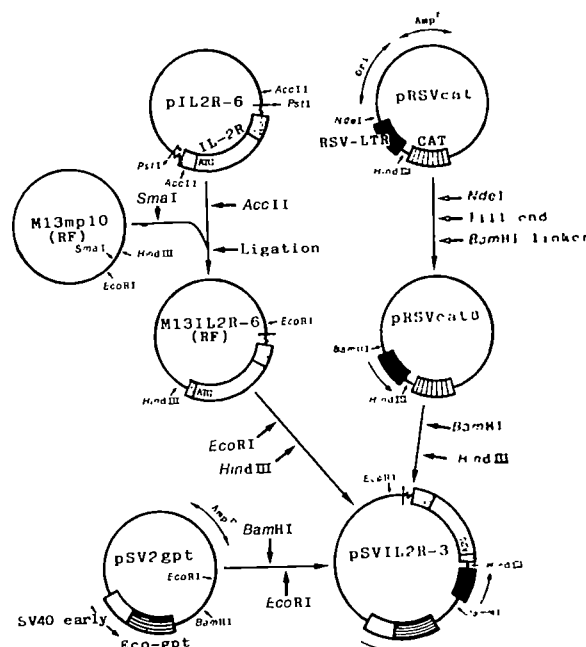

Fig. 1 Construction of the expression plasmid for human IL-2 receptor cDNA. A cDNA library complementary to poly(A)⁺ mRNA of activated human lymphocytes was constructed essentially as described previously¹⁸. Based on the published cDNA sequences for the human IL-2R¹⁴⁻¹⁶, oligonucleotide probes were synthesized and these were used to screen the cDNA library. A clone, pIL2R-6, which contains the entire coding sequence for human IL-2R, was obtained. pIL2R-6 was digested with AccII and a 1.55-kilobase (kb) IL-2R cDNA fragment was isolated. This fragment was then ligated to the SmaI site of M13 phage mp10 (M13IL2R-6). For the preparation of RSV LTR, pRSVcat²¹ was cleaved with NdeI and, after filling-in both ends using DNA polymerase I, a synthetic BamHI linker was introduced (pRSVcatB). Then the 1.6-kb EcoRI-HindIII IL-2R cDNA fragment derived from M13IL2R-6, the 0.6-kb BamHI-HindIII RSV LTR fragment derived from pRSVcatB and the EcoRI-BamHI-cleaved pSV2gpt were ligated by T₄ DNA ligase to construct pSVIL2R-3.

cloned from normal lymphocytes. A mouse T-lymphocytic line, EL-4, expressed human IL-2R with high (dissociation constant (K_d) = 160-220 pM) and low (K_d = 2.1-2.2 nM) affinity for recombinant human IL-2, while mouse L929 cells expressed only a single class of the IL-2R with lower affinity (K_d = 34.5 nM) for the ligand. We also show that the human IL-2R expressed in EL-4 cells responds to IL-2 and mediates reversed signal transduction: growth of the EL-4 cells harbouring the IL-2R is inhibited specifically by human recombinant IL-2. The approach described here may provide a general experimental framework for elucidating the molecular basis of signal transduction mediated by specific receptor-ligand interaction.

We prepared a cDNA library using poly(A)⁺ RNA from activated human lymphocytes¹⁸ and screened it for IL-2R (Tac-antigen)-specific clones with oligonucleotide probes. Among several positive clones identified, clone pIL2R-6 was analysed and shown to contain a nucleotide sequence encoding a complete polypeptide identical to that of aberrantly expressed IL-2R in leukaemic cells derived from adult T-cell leukaemia (ATL), reported previously by others¹⁴⁻¹⁶ (data not shown).

Recent studies using radiolabelled IL-2 demonstrated the existence of two classes of IL-2R that differ in their affinities for IL-2 (refs 5, 6). The finding that IL-2-induced T-cell proliferation correlates well with the expression of the high-affinity receptor suggests that the high-affinity receptor alone is capable of signal transduction^{1,2,5}. Although it was reported previously that the cloned human IL-2R cDNA can direct the expression of a cell-surface molecule capable of binding both IL-2 and a monoclonal anti-human IL-2R antibody, anti-Tac^{19,20}, in cultured monkey kidney (COS) cells^{14,15}, it was unclear whether that molecule was functioning as IL-2R, that is, whether it

Fig. 2 Flow microfluorimetric analysis of mouse cells expressing either human or mouse IL-2 receptor. Mouse cells were stained indirectly with either mouse anti-human IL-2R monoclonal antibody, anti-Tac (*a-e*), or rat anti-mouse IL-2R monoclonal antibody, AMT-13 (*f-j*). Cells used for staining were as follows: *a, f*, EL-4; *b, g*, ELT-5 (an EL-4 transformant); *c, h*, ELT-13 (an EL-4 transformant); *d*, L929; *e, i*, LCT-4 (an L929 transformant); *j*, concanavalin A-activated splenocytes (Con A blasts) of CBN mouse origin. Dotted lines represent staining with the fluorescent second-step conjugate alone.

Methods. Cells (5×10^5) were incubated in 50 μ l Hank's balanced salt solution containing 0.1% bovine serum albumin and 0.1% NaN_3 (HBSS-BN) for 30 min at 4°C with saturating concentrations of anti-Tac (1:500 dilution of ascites fluid) or AMT-13 (1:500 dilution of ascites fluid). After incubation, cells were washed three times, then resuspended in 40 μ l HBSS-BN containing appropriate concentrations of fluorescein-conjugated goat anti-mouse IgG or mouse anti-rat κ -chain for 30 min at 4°C. Then the cells were washed three times, resuspended in 0.5 ml HBSS-BN and analysed using a FACS 440 (Becton Dickinson). Con A blasts were prepared as described previously²⁵. EL-4 transformants were produced by transfecting pSVIL2R-3 into EL-4 by the protoplast fusion technique essentially as described by Oi *et al.*³². Mycophenolic acid ($4 \mu\text{g ml}^{-1}$)-resistant colonies were visible by 10–14 days; these cells were cloned by the limiting dilution method. Transfection of pSVIL2R-3 into L929 cells was done using the calcium phosphate technique as described by Chu and Sharp³³. After 3 weeks, mycophenolic acid ($2.5 \mu\text{g ml}^{-1}$)-resistant cells were collected, stained indirectly with anti-Tac antibody and the positive cells were cloned by single-cell manipulation using FACS, as described by Parks *et al.*³⁴.

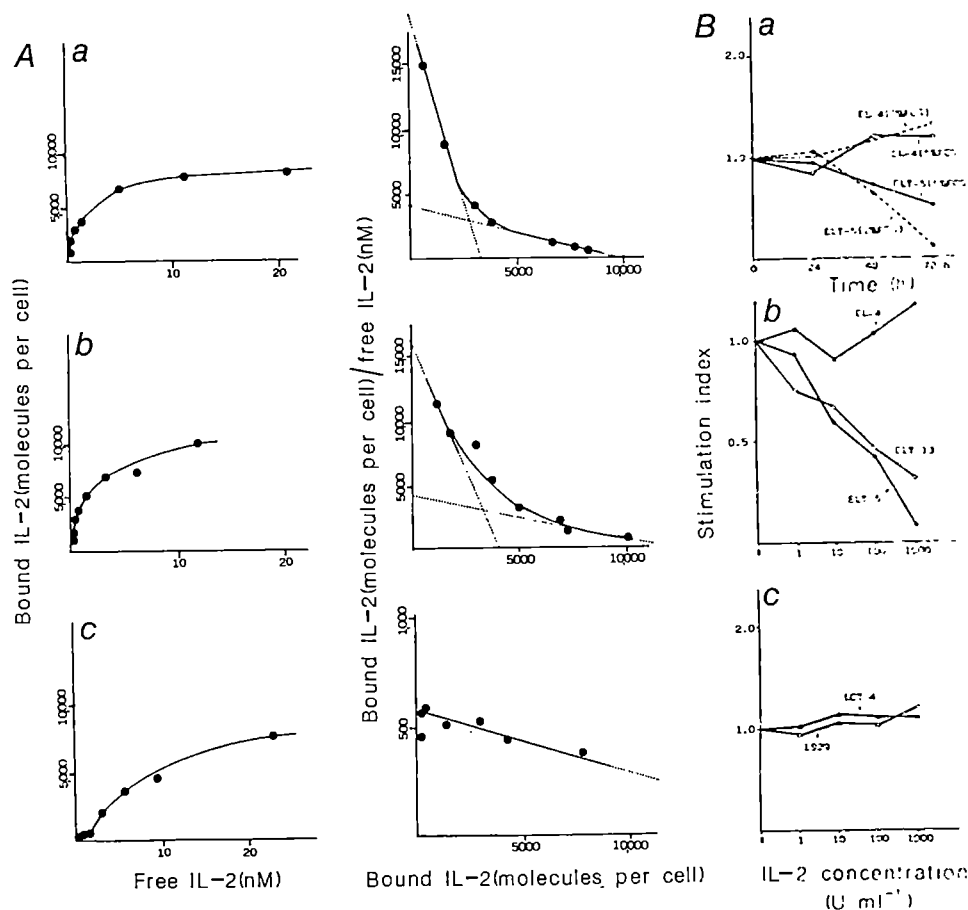

exhibited high affinity for IL-2 and delivered the IL-2-specific signal.

To express the IL-2R cDNA stably in mammalian cells, we first constructed a plasmid, pSVIL2R-3, as shown in Fig. 1. Into this plasmid we inserted the long terminal repeat (LTR) sequence of Rous sarcoma virus (RSV)²¹ just upstream of the IL-2R cDNA and introduced this chimaeric gene into the pSV2gpt vector²². This plasmid was transfected into EL-4 cells, a benzo[*a*]pyrene-induced thymoma line²³, and into mouse L929 cells, a transformed fibroblast cell line. Transformants were selected in medium containing mycophenolic acid (MPA) and cells expressing the human IL-2R (Tac antigen) were cloned. Blotting analysis of the DNA prepared from each of 16 EL-4 and 10 L-cell transformant clones indicated the presence of one to two copies of the transfected human cDNA (data not shown). Three of these transformed cell clones, ELT-5, ELT-13 (EL-4 origin) and LCT-4 (L929 origin), were arbitrarily chosen for further analysis. As shown in Fig. 2*a-e*, immunofluorescent staining profiles clearly demonstrate the expression of Tac anti-

gen on the cell surface of IL-2R cDNA transformants, while parental cells are negative for the same antigen.

To determine whether the human IL-2R expressed on the surface of murine cell transformants manifests high or low affinity for IL-2, we performed radiolabelled IL-2 binding assays. Scatchard plot analysis of two EL-4 transformants showed curvilinear features, demonstrating the presence of two distinct receptors having different binding affinities for recombinant IL-2, with dissociation constants of 160 and 2,100 pM in ELT-5, and 220 and 2,200 pM in ELT-13 (Fig. 3*A, a, b*). This result was highly reproducible and, in our assay system, the K_d of the high-affinity receptor expressed on activated human T lymphocytes and some ATL cells falls within the range 10–100 pM⁶. Thus, the K_d of the high-affinity receptor expressed on the heterologous mouse cell transformants is only slightly lower than that of the endogenous high-affinity receptor on human cells, and the K_d of the second class of receptors expressed on transformant cells is also similar to that of the low-affinity receptor expressed on human cells⁶. In contrast to the EL-4

Fig. 3 **A**, IL-2 binding assay. EL-4 and L929 cell transformants expressing human IL-2R were examined for their IL-2 binding activities using radiolabelled human IL-2. ELT-5 (**a**) and ELT-13 (**b**) were derived from EL-4, and LCT-4 (**c**) was derived from L929. The binding curve of radiolabelled IL-2 (left) and the Scatchard plot analysis of the IL-2 binding data (right) are shown. Human recombinant IL-2 (purity >99.8%) was radiolabelled using ^{125}I -Bolton and Hunter's reagent. The specific radioactivity of the labelled IL-2 was 2,000–5,000 c.p.m. ng^{-1} . The ^{125}I -IL-2 binding assay was performed using methods described by Robb *et al.*⁵, with slight modifications⁶. Serial dilutions of radiolabelled IL-2 and 2×10^6 cells were incubated for 40 min at 37 °C in a total volume of 0.5 ml of RPMI 1640 medium containing 25 mM HEPES, 1% bovine serum albumin (BSA) and 0.1% sodium azide. After the incubation, cells were washed and resuspended in the same medium. The cell suspension (200 μl) in duplicate was layered over 150 μl of a mixture of 20% olive oil and 80% di-n-butylphthalate. Following centrifugation of samples, the tips of the sample tubes containing the cell pellets were cut off and the radioactivities were measured using a γ -counter. Nonspecific binding was determined by incubating cells in the presence of a 300-fold excess of unlabelled IL-2. Specific binding was obtained by subtracting nonspecific binding, which represents ~10% of the total binding. **B**, Effect of human recombinant IL-2 on the mouse cells expressing human IL-2R. **a**, Time course kinetics of the effect of IL-2 (1,000 U ml^{-1}) on the growth of EL-4 (\circ) and ELT-5 (\bullet) in medium supplemented with 2% (—) and 5% (---) fetal calf serum (FCS). **b**, **c**, Dose-response curves of IL-2. Cells were cultured for 72 h in medium containing 10% FCS in the presence of various concentrations of IL-2. Cells used were EL-4 (\blacksquare), ELT-5 (\bullet), ELT-13 (\circ), L929 (Δ) and LCT-4 (\blacktriangle). EL-4 and its transformants, ELT-5 and ELT-13, were grown in RPMI 1640 medium supplemented with 10% FCS. L929 and the transformant LCT-4 were cultured in ES medium (Nissui) containing 10% FCS. Cells collected from the culture were plated at 1×10^3 per well in 96-well flat-bottomed microculture plates. Cells were cultured in RPMI 1640 or ES medium in the presence of various concentrations of human recombinant IL-2. Half of the medium was aspirated daily and was replaced with fresh medium containing the same supplements; 4 h (EL-4 and its transformants) or 8 h (L929 and LCT-4) before the termination of culture, 1 μCi of ^3H -thymidine (^3H -TdR) was added to each culture well. Then cells were placed on glass fibre strips using an automatic cell harvester and ^3H -TdR incorporation was measured as an index of cell proliferation. Results are expressed as a stimulation index (SI) = c.p.m. ^3H -TdR incorporation with IL-2/c.p.m. ^3H -TdR incorporation without IL-2. The specific activity of the human recombinant IL-2 was 5×10^7 U per mg protein.

transformants, a mouse L929 transformant, LCT-4, expressed only a low-affinity receptor having a K_d of 34.5 nM (Fig. 3A, c); interestingly, this value is one order of magnitude higher than that of the low-affinity receptor expressed on the EL-4 transformants. The total number of IL-2R molecules per cell was approximately 9,000, 12,000 and 20,000 for ELT-5, ELT-13 and LCT-4, respectively (Fig. 3A). As regards the high-affinity receptor, we found 3,000 molecules per cell in ELT-5 and 4,500 molecules per cell in ELT-13. Thus, the number of IL-2R molecules expressed in these transformants is similar to that of activated human T cells and one order of magnitude lower than that of leukaemic T cells such as MT-1 or HUT-102 (refs 5, 6). As mouse IL-2R is known to react with human IL-2 (ref. 24), we determined whether EL-4 cells and the transformants express mouse IL-2R on their surface. A binding assay using ^{125}I -labelled human recombinant IL-2 demonstrated no significant binding of IL-2 with parental EL-4 cells (data not shown). Moreover, fluorescence-activated cell sorter (FACS) analysis using rat anti-mouse IL-2R monoclonal antibody, AMT-13 (ref. 25), revealed no mouse IL-2R (Fig. 2f–j). These results demonstrate that high-affinity human IL-2R can be reconstituted in heterologous host cells by expression of the cDNA encoding the Tac antigen and that expression of the high-affinity IL-2R requires a T-cell-specific background.

The fact that introduction of human IL-2R cDNA into EL-4

cells leads to constitutive expression of the high-affinity receptor for human IL-2 prompted us to examine whether the human IL-2/receptor system delivers the signal transduction in mouse cells. When recombinant human IL-2 was added to culture media of the transformants, it inhibited the growth of ELT-5 and ELT-13 cells, as expressed by incorporation of ^3H -thymidine into DNA, but had no significant effect on parental EL-4 cells (Fig. 3B, a, b). The growth inhibition of EL-4 transformants was evident at an IL-2 concentration of 1–10 U ml^{-1} (~1.3–13.0 pM), at which concentration IL-2 should bind only to the high-affinity receptor (Fig. 3B, b). Thus, it is likely that the signal transduction is mediated through the high-affinity receptor. At a higher concentration of IL-2 (1,000 U ml^{-1} ; 1.3 nM), a reduction of almost 90% in ^3H -thymidine incorporation was observed. At this IL-2 concentration, growth of the EL-4 transformants was detectably inhibited by 48 h after the onset of culture with IL-2 and ceased almost completely by 72 h (Fig. 3B, a). Cell viability at that time was over 95% and cell proliferation was resumed after removal of IL-2 from the culture media (data not shown). This growth inhibition was not due to growth inhibitory substances whose production is induced by IL-2, as growth of parental EL-4 cells was not inhibited by co-cultivation with ELT-5 or ELT-13 in the presence of 1,000 U ml^{-1} IL-2 (data not shown). In contrast to the observations with these EL-4 transformants, no significant growth alteration was observed for either LCT-4 cells or parental

Table 1 Effect of anti-Tac antibody on the IL-2-induced growth inhibition of ELT-5 cells

Cell line	Treatment		c.p.m. (mean \pm s.d.)	SI
	IL-2	Anti-Tac		
EL-4	-	-	27,600 \pm 1,300	1.00
	500 U ml ⁻¹	-	29,900 \pm 2,200	1.08
	-	1 μ g ml ⁻¹	27,700 \pm 2,400	1.00
	500 U ml ⁻¹	1 μ g ml ⁻¹	29,500 \pm 1,900	1.07
ELT-5	-	-	29,900 \pm 1,300	1.00
	500 U ml ⁻¹	-	5,100 \pm 500	0.17
	-	1 μ g ml ⁻¹	29,700 \pm 4,300	0.99
	500 U ml ⁻¹	1 μ g ml ⁻¹	27,800 \pm 1,300	0.93

The cell proliferation assay was performed as described in the legend to Fig. 3B. Anti-Tac antibody was added at the onset of culture. After 24 and 48 h, half of the medium was removed from each culture and replaced with fresh medium containing the same supplements (IL-2 and/or anti-Tac). After 72 h, 1 μ Ci of ³H-thymidine was added to each culture well, incubation was continued for a further 4 h and the ³H-thymidine incorporation was measured. The stimulation index (SI) was determined as follows; SI = ³H-thymidine incorporation with treatment/³H-thymidine incorporation without treatment.

L929 cells (Fig. 3B, c). As stated above, EL-4 and its transformants do not detectably express mouse IL-2R on their cell surface, therefore growth inhibition of the EL-4 transformants induced by human recombinant IL-2 is most likely mediated by the human IL-2R. This conclusion is reinforced by the finding that the addition of anti-Tac antibody to culture medium containing IL-2 restores almost completely the growth of ELT-5 cells (Table 1). As expected, AMT-13, which recognizes the mouse IL-2R and blocks IL-2-dependent murine T-cell growth²⁵, had no effect on the human IL-2-mediated growth inhibition of ELT-5 (data not shown).

Bifunctional properties of growth factors have been reported also for other growth factor/receptor systems such as that of epidermal growth factor (EGF)^{26,27} and transforming growth factor type β ²⁸. Growth of A431 human epidermal carcinoma cells, which express an unusually high number of EGF receptors, is inhibited in the presence of a high concentration of EGF²⁶. The mechanism of growth inhibition in that system may be related to overstimulation of receptor-associated tyrosine kinase²⁷. As the intracytoplasmic portion of the IL-2R is too short to mediate any kinase activity¹⁴⁻¹⁶, the mechanism of growth inhibition reported here is likely to be different. Recently, high concentrations of IL-2 were reported to inhibit growth of some but not all HTLV (human T-cell lymphotropic virus)-infected T-cell clones, by interacting with IL-2R²⁹. It is illuminating that the growth factor/receptor interaction in neoplastic cells, which are capable of uncontrolled cell proliferation, often leads to reversal of the growth stimulatory signal. As we used a viral LTR sequence for the IL-2R cDNA expression, a 'down-regulatory' mechanism of the heterologous receptor will not operate. Indeed, the level of IL-2R mRNA and Tac-antigen remained unchanged in the presence of IL-2 in ELT-5 cells (our unpublished observations). Thus, continuous growth factor/receptor interaction on the cell surface may also account for the inhibition of the uncontrolled cell growth. Such a reversed signal transduction may be delivered by activation of protein kinase C via a high-affinity receptor³⁰.

The expression of functional, specific receptor molecules introduces a powerful new tool for the investigation of ligand-receptor interactions, and especially for extending our understanding of molecular mechanisms of signal transduction by means of site-directed mutagenesis of the cloned genes and functional study of the gene product.

After submission of this manuscript, Greene *et al.* reported the expression of low-affinity IL-2Rs in mouse L-cells³¹.

We thank Drs J. Hamuro, T. Diamantstein and H. Osawa, B. Howard, P. Berg and H. Matsui for supplying recombinant IL-2, AMT-13, pRSVcat, pSV2gpt and oligonucleotide probes, respec-

tively. We also thank Drs T. Kishimoto, R. Kaempfer, I. Yahara, K. Smith, K. Kumagai, K. Yamasaki and T. Fujita and Ms M. Nagatsuka for help and useful comments. This work was supported in part by a grant-in-aid for Special Project Research, Cancer-Bioscience from the Ministry of Education, Science and Culture of Japan.

Human blood platelets showing no response to collagen fail to express surface glycoprotein Ia

H. Karel Nieuwenhuis, Jan Willem N. Akkerman, Wim P. M. Houdijk & Jan J. Sixma

Department of Haematology, University Hospital Utrecht, Catharijnesingel 101, 3511 GV Utrecht, The Netherlands

The interaction of blood platelets with collagen is generally considered to be of primary importance in the arrest of bleeding and to have a role in the pathogenesis of thrombosis and atherosclerosis. Following damage to the vascular endothelium, circulating platelets come into contact with exposed collagen fibrils in the sub-endothelium and spread along it; this is followed by the secretion of several biologically active substances and by aggregation of platelets. The glycoproteins of the platelet plasma membrane have an important role in the mechanisms underlying these processes. So far, two specific defects of platelet function in patients with a bleeding disorder are known to be associated with a glycoprotein defect and the study of these patients has contributed significantly to present concepts of platelet function. The glycoprotein (GP) IIb-III complex, absent or deleted in the aggregation-defective Glanzmann's thrombasthenia¹, has been identified as the platelet fibrinogen receptor. GPIb, which is absent in the adhesion-defective Bernard-Soulier syndrome^{2,3}, has been identified as the von Willebrand factor receptor on platelets. We now report a defect of the platelet plasma membrane glycoprotein composition in a patient whose platelets are totally unresponsive to collagen.

Fig. 1 Aggregation tracings of patient's platelet-rich plasma. Aggregation studies were performed at 37 °C and were normal in response to ADP (1 and 5 μ M), A23187 (5 and 10 μ M), adrenaline (5 μ M), arachidonic acid (1.5 mM), PAF-ACE (1 μ M) and ristocetin (1 mg ml⁻¹). Collagen induced neither shape change nor aggregation.

We studied the platelets of a patient with a haemorrhagic disorder and an excessively long bleeding time (>30 min, compared with the normal range of up to 8 min). Platelet count, coagulation studies and factor VIII parameters were normal. With the informed consent of the patient and control subjects, venous blood was collected in 0.1 vol. of 135 mM trisodium citrate. For some experiments the platelets were isolated by passage through a Sepharose 2B column (Pharmacia) equilibrated in Ca²⁺-free Tyrode's solution (pH 7.2). Aggregation in the patient's platelet-rich plasma (PRP) (Fig. 1) was normal in response to ADP, the ionophore A23187, adrenaline, arachidonic acid, PAF-ACE (platelet aggregating factor/alcohol-chloroform-ether mixture) and ristocetin. Thrombin-induced aggregation was normal in gel-filtered platelet suspensions. In contrast collagen induced neither shape change nor aggregation in PRP and gel-filtered platelet suspensions. This result was found consistently for both low and very high concentrations of several types of fibrillar collagen: equine collagen type I (1–10 μ g ml⁻¹), bovine collagen types I (5–100 μ g ml⁻¹) and III (50–100 μ g ml⁻¹) as well as with purified human collagen types I and III (10–100 μ g ml⁻¹). Normal platelets aggregated with the lowest concentrations of these collagen types. Experiments in which PRP from the patient was mixed with control platelet-free plasma or in which platelet-free plasma from the patient was added to control PRP, demonstrated the absence of a circulating inhibitor and suggested that the defect resided in the platelets.

As current data suggest that the breakdown of phosphatidylinositol (PI) with concurrent formation of diacylglycerol and phosphatidic acid (PA) might be an early common mechanism whereby activation of receptors brings about physiological responses, we studied the metabolism of PI in the patient's platelets (Table 1). In normal platelets labelled with ³²P-orthophosphate, stimulation caused an increase in the ³²P content of PA and PI, which suggests that the PA formed recycles to PI. Treatment of normal ³H-arachidonate-labelled platelets with thrombin or collagen caused loss of radioactivity from PI, with a corresponding accumulation of radioactive PA, free arachidonate and its oxygenation products. In the patient's platelets, thrombin (5 U ml⁻¹) induced a normal decrease of ³H-PI, a normal accumulation of ³²P-PA, a normal incorporation

Table 1 Changes in distribution of label in platelets prelabelled with ³²P-orthophosphate and ³H-arachidonate after stimulation (5 min, 37 °C) with thrombin (5 U ml⁻¹) or collagen (10 μ g ml⁻¹)

	Controls	Patient	
Thrombin			
³ H-PI	33 ± 7%	44%	NS
³² P-PI	146 ± 21%	155%	NS
³² P-PA			
(before exposure)	3,200 c.p.m. per 10 ⁹ pl.	2,100 c.p.m. per 10 ⁹ pl.	
(after exposure)	76,100 c.p.m. per 10 ⁹ pl.	44,300 c.p.m. per 10 ⁹ pl.	
Collagen			
³ H-PI	59 ± 9%	98%	<i>P</i> < 0.05*
³² P-PI	133 ± 15%	95%	<i>P</i> < 0.05*
³² P-PA			
(before exposure)	3,200 c.p.m. per 10 ⁹ pl.	2,100 c.p.m. per 10 ⁹ pl.	
(after exposure)	32,400 c.p.m. per 10 ⁹ pl.	2,000 c.p.m. per 10 ⁹ pl.	

Data are expressed as a percentage (mean ± s.d.) of the radioactivity before activation for ³H-PI and ³²P-PI (for controls, *n* = 5) and, because of low basal values, are given as c.p.m. per 10⁹ platelets (pl.) for ³²P-PA. The ³²P-PA control data are representative of 10 controls studied. Platelets were incubated with 0.01 μ M ³H-arachidonate (specific activity 90 Ci mmol⁻¹; TRK, Amersham International) and 0.1 mCi (carrier-free) H₃³²PO₄ (NEN) for 60 min at 37 °C. Twenty per cent of the radiolabelled arachidonate was taken up by the platelets. After gel filtration the labelled platelets were incubated with thrombin or collagen for 5 min. Extracts were obtained and the phospholipids, fatty acids and thromboxanes were separated by TLC as described elsewhere¹⁹. The ³H and ³²P content of the fractions was determined by scintillation counting.

* Significant difference by Student's *t*-test; NS, not significant (*P* > 0.05).

of ³²P in PI and a normal liberation of ³H-arachidonic acid. Changes in the PI cycle and liberation of ³H-arachidonic acid were not observed after exposure of the patient's platelets to collagen. Thromboxane B₂ (TXB₂) was produced normally in the patient's PRP in response to exogenous arachidonate (1.5 mM), as determined by radioimmunoassay. After incubation for 1 min, the patient's PRP generated 540 nmol TXB₂ per 10¹¹ platelets (normal range 110–518 nmol per 10¹¹ platelets, *n* = 8). There was no detectable TXB₂ generation on stimulation of the patient's platelets with collagen for 5 min (patient < 2, normal range 90–142 nmol per 10¹¹ platelets, *n* = 8).

The interaction of blood platelets with purified human fibrillar collagen type I in a static system was studied according to Legrand⁴ using a technique based on gel filtration of non-adhesive platelets through a Sepharose 2B column after incubation of PRP with fibrillar collagen. For the slightly modified test used here, 0.8 ml of PRP (4 × 10⁵ platelets μ l⁻¹), obtained from EDTA-blood to prevent aggregation, was incubated (37 °C, 2.5 min, without stirring) with 0.2 ml of 0.02 M sodium phosphate buffer pH 7.4 with and without 100 μ g of purified human collagen type I, made fibrillar as described elsewhere⁵. The mixtures were applied to a Sepharose 2B column, equilibrated in a Ca²⁺-free Tyrode's solution, pH 7.4, containing 20 mM HEPES and 0.2% (w/v) bovine serum albumin. The platelets were counted before and after passage and the percentage adhesion calculated. After incubation of the patient's platelets with collagen and subsequent gel filtration, almost no platelets were retained with the collagen fibrils at the top of the column: there was 4.4 ± 0.7% adhesion in the patient, 83.4 ± 1.0% in the control (mean ± s.d. of triplicate experiments). This severe defect in adhesion is present in a static system, where platelet transport towards collagen occurs as a result of diffusion and gravitation, and consequently it differs from the shear-dependent adhesion defects in von Willebrand's disease and Bernard-Soulier syndrome.

Fig. 2 Autoradiograms (*a, b*) and silver staining (*c, d*) of two-dimensional reduced SDS-polyacrylamide gels for control (*a, c*) and patient (*b, d*) platelets. The positions of the major membrane glycoproteins are indicated. Note that GPIa is lacking in the patient. Values shown on the right-hand side in *b* are $M_r \times 10^{-3}$. **Methods.** Platelets were radioiodinated in parallel by using Iodogen (Pierce Chemicals, Rockford, Illinois) as a catalyst. Isoelectric focusing, SDS-polyacrylamide gel electrophoresis (3–30% acrylamide linear gradient gels) and autoradiography of the gels were performed as described elsewhere²⁰. Gels were silver-stained using a technique described previously²¹.

Analysis of the platelet ectoproteins by silver staining and ¹²⁵I surface labelling, coupled with one- and two-dimensional gel electrophoresis, disclosed a deficiency of the membrane glycoprotein Ia (relative molecular mass (M_r) 168,000 under reducing conditions, pI 4.8–5.4) (Fig. 2). Similar results were obtained when repeated labellings of the patient's platelets were compared with the autoradiograms obtained from 10 controls. Extreme overexposure of the autoradiograms revealed a small amount of residual radioactivity in the GPIa region. To quantitate the amount of label in GPIa, this glycoprotein was marked in the gels by autoradiography, cut out of the two-dimensional gels, and counted in a scintillation counter. Several other glycoproteins in the gels were used as standards. Consistent results were obtained on radiolabelling of normal platelets (GPIIb/GPIIIb = 0.35 ± 0.04 (\pm s.d.); GPIa/GPIIIb = 0.22 ± 0.06 , $n = 5$). Repeated simultaneous labelling studies of the patient's platelets revealed 15–25% of the normal level of GPIa. Low but detectable amounts of GPIb (7–30%) and GPIIb–III (12–25%) have been found in some patients with Bernard-Soulier syndrome^{3,6,7} and Glanzmann's thrombasthenia^{8,9}. These patients, referred to as type 2, suffer from a bleeding syndrome and have abnormal (absent) aggregation responses. The defect in the patient studied here—a complete lack of response to collagen associated with a markedly reduced concentration of GPIa—resembles these corresponding platelet function defects in this respect.

GPIa is an ectoprotein which contains intramolecular disulphide bonds as it has an increased apparent relative molecular mass after disulphide cleavage. GPIa is weakly stained by the periodic acid-Schiff reaction, weakly radiolabelled by the perio-

date method and is hardly affected by treatment with neuraminidase, which indicates that it contains a relatively low concentration of sialic acid. GPIa binds to the lectin wheat-germ agglutinin (*N*-acetylglucosamine specificity)¹⁰.

A putative role as the platelet receptor for collagen has been proposed for glucosyltransferase¹¹, fibronectin¹², complement component C1s¹³, a protein of M_r 65,000 (ref. 14), and glycoprotein IIb¹⁵. Subsequent studies, however, do not confirm such a role for glucosyltransferase^{16,17} or for fibronectin¹⁸ and it is unlikely that GPIIb serves as a collagen receptor, as in Glanzmann's thrombasthenia (a disorder with a deficiency of the fibrinogen receptor, GPIIb–GPIIIb), collagen-induced shape change and release are normal. In the case of the patient studied here it is evident that the primary interaction of the platelet with collagen is disturbed. In contrast to collagen, several other agonists induced normal physiological responses in the patient's platelets. These results indicate that after exposure to collagen, information could not be transmitted across the plasma membrane to trigger the intracellular events. The observed membrane abnormality occurs in parallel with the lack of responsiveness to collagen, which suggests a cause and effect relationship. Consequently, GPIa may have a receptor or transmitter function.

We thank Marion Schiphorst, Gertie Gorter and Jeanne Korteweg for technical assistance. This work was supported by the Netherlands Organization for the Advancement of Pure Research (ZWO/Fungo) under grant 13-30-92.

Specific growth response of *ras*-transformed embryo fibroblasts to tumour promoters

Gián Paolo Dotto, Luis F. Parada & Robert A. Weinberg

Whitehead Institute for Biomedical Research, Nine Cambridge Center, Cambridge, Massachusetts 02142, USA

Chemical carcinogenesis is a process involving multiple steps, as shown in several *in vivo* experimental systems¹. Two early steps have been well characterized: initiation, achieved by a single, subthreshold dose of a carcinogen, and promotion, induced by repetitive treatments with a non-carcinogenic tumour promoter. At the cellular level, establishment of the transformed phenotype is also a multi-step process and activation of several, independent genes appears to be required^{2–4}. Here we show that, like initiated cells, primary rat embryo fibroblasts (REFs) containing a *ras* but

Fig. 1 Effect of TPA on focus formation of oncogene-bearing REFs in monolayer. Tertiary rat embryo fibroblasts (7×10^5 cells per 10-cm dish) were infected with the SVX, raszip 6 or VM viruses (MOI = 0.1–1). After 48 h, cells were split 1:10 into normal medium (Dulbecco's modified essential medium/10% fetal bovine serum), medium plus TPA (10 ng ml^{-1}), or medium plus G418 (0.5 mg ml^{-1}). Dishes were fixed and stained 10 days later.

not a *myc* oncogene, are strongly and specifically stimulated to grow by tumour promoters. In the presence of these promoters, *ras*-containing REFs acquire the ability to overgrow normal cells in the monolayer and to form foci with 100% efficiency. Similar to the *in vivo* situation, promoter effects can be blocked by the concomitant application of retinoic acid.

One of the best *in vivo* models for chemical carcinogenesis is represented by the mouse skin system^{1,5,6}, in which a minimum of two genetic lesions seems to be involved in tumour formation⁷. An apparent parallel arises from the observation that full transformation of primary embryo fibroblasts in culture occurs after introduction of two genetic elements—a *ras*-like and a *myc*-like oncogene. Cells bearing the two oncogenes are fully tumorigenic *in vivo*.

The mouse skin model of initiation and promotion carries specific implications for the action of the promoter and its effects on initiated cells⁵. According to this model, the initiating carcinogen creates a small number of initiated cells, each one bearing a lesion in a specific gene. The promoter then acts to induce the clonal expansion of each initiated cell, which results in a large descendant population, in one cell of which a rare second genetic lesion may now occur. On this basis, an initiated cell is one which enjoys a special growth advantage in the presence of a promoter; and a promoter is a compound that selectively stimulates the outgrowth of already initiated cells.

We reasoned that activation of a *ras*-like or *myc*-like oncogene might represent the initiating event. As a model in which to test this hypothesis, we produced REFs carrying either a *ras* or a *myc* oncogene. We aimed to measure whether either of these cell types enjoyed a special growth advantage in the presence of a tumour promoter such as TPA (12-*O*-tetradecanoylphorbol-13-acetate).

Cells carrying recently introduced oncogenes are often elusive in REF cultures, as their presence is not always signalled by the outgrowth of a focus of transformants². Therefore, we additionally marked these cells with the gene which confers resistance to killing by the antibiotic G418 (ref. 8). This would allow us to quantitate the number of oncogene-bearing cells in a culture at any point by measuring the number that were resistant to the antibiotic (G418^r).

Fig. 2 Effect of TPA on the growth of oncogene-bearing REFs in monolayer. REFs were infected as described in Fig. 1 legend. After 48 h the cells were split 1:10 into either normal or TPA-containing medium and separate dishes were withdrawn at various times after that. Cells were trypsinized, counted and re-plated at a density of 1 and 5×10^5 cells per 10-cm dish in G418-containing medium (0.5 mg ml^{-1} ; Gibco). Colonies were counted after 2 weeks and the ratio of the number of colonies from cells grown with TPA to the number from cells grown without TPA was calculated. Two independent dishes were scored for each experimental point. Values are given for cells infected with raszip 6 (●), VM (○) and SVX (▲).

In previous work with REFs, DNA transfection had been used to introduce oncogenes². However, the efficiency of gene transfer by this method is low, and the number of transfected cells hard to control. Therefore, we used retrovirus vectors to convey both oncogenes and the G418^r marker into these cells. By transfecting the resulting viral genomes into $\psi 2$ cells⁹, we obtained high-titre recombinant viruses that were free of helper. These vectors could introduce oncogenes into REFs but would not allow virus spread beyond the initially infected cell.

One retrovirus carrying the *ras* oncogene was constructed by inserting the viral Ha-*ras* gene (map positions 4,000–4,710; ref. 10) into the *Bam*HI site of SVX, a retroviral vector already containing a G418-resistance gene¹¹. The DNA construct was transfected into $\psi 2$ cells⁹, resulting in a virus stock (raszip 6) showing a high titre of induction of G418 resistance (10^6 – 10^7 colony-forming units ml^{-1}). When the virus was tested on established NIH 3T3 mouse cells, acquisition of resistance to G418 was always accompanied by a morphological transformation characteristic of that induced by the *ras* oncogene. A second virus used in these studies, VM, carries the *myc* oncogene (p110 *gag-myc* fusion gene from pv-*myc*²) in addition to the G418^r marker. This virus induces expression of *myc* transcript and protein and is able to immortalize REFs in preparation). As a control, we used the SVX virus¹¹, which carries only the G418 resistance marker and no oncogene.

Third-passage REFs were infected with the three viruses at various concentrations and after 2 days were split into two groups which were then grown in either normal medium or medium containing G418 (0.5 mg ml^{-1}). After incubation for 1 week, dishes were scored either for foci or for colony formation in selective medium.

No foci could be detected in monolayers carrying the *myc* virus, independent of the multiplicity of infection (MOI). Similarly, when the *ras* virus was applied at moderate MOI, resulting in the infection of only 0.1–1% of the cells, no foci were seen. This result agrees with earlier work in which transfection was used to introduce the *ras* oncogene into a small proportion of the REF cells, yielding no observable foci².

We then assessed the effects of TPA on these various populations of oncogene-bearing and normal cells. TPA was used at

Fig. 3 Effect of TPA on the growth of oncogene-bearing REFs in the absence of surrounding normal cells. Cells were infected as described in Fig. 1 legend and after 48 h were split 1:10 into G418-containing medium (0.5 mg ml^{-1}), with or without TPA (10 ng ml^{-1}). Dishes were stained 1 week later.

10 ng ml^{-1} , a concentration comparable to that normally used to study the physiological effects of this substance on cells in culture¹².

TPA had no effects on the ability of SVX or *myc*-bearing cells to form foci in the monolayer (Fig. 1). In contrast, the effects on *ras*-bearing cells were dramatic, in that large numbers of foci of morphologically transformed cells were now apparent in the monolayer (Fig. 1). Significantly, the number of foci closely approximated the number of G418^r colonies obtained from the same cell population when plated on selective medium (Fig. 1). Most of the cells in these colonies showed a transformed morphology (data not shown). Thus, almost every cell that expressed the G418^r gene of the raszip 6 chimera was also able to form a focus in the presence of TPA. This ability of TPA to affect all the '*ras* cells' present in the monolayer conforms to epigenetic effects associated with promoters and contrasts with the rarely occurring genetic alterations associated with initiating agents¹.

The appearance of these foci suggested that the tumour promoter allowed the *ras* transformants to overcome the growth inhibitory effect imposed on them by the surrounding monolayer of normal cells. We wished to substantiate this view by direct measurement of the number of *ras* (or *myc*)-transformed cells growing in these culture conditions. Cultures infected with SVX or *ras* or *myc* virus were grown for various times in the presence or absence of TPA, then trypsinized and part of them re-plated in the presence of G418, but with no TPA in the medium. This allowed us to measure the proportion of SVX, *ras* or *myc*-bearing cells in the population, independently of any assay of focus-forming ability. It is clear from Fig. 2 that the proportion of '*myc*-cells' was not substantially affected by the presence of TPA. Similarly, the proportion of control SVX-infected cells was also not changed by TPA. In contrast, the proportion of '*ras*-cells' in the cell population was much greater in the presence of the tumour promoter; it was 4-fold higher than the control 3 days after the beginning of the experiment, 10-fold higher at 5 days and 20-fold higher at 7 days. This result demonstrates directly that the clonal expansion of cells containing a *ras*, but not a *myc* oncogene, is strongly and preferentially stimulated by the presence of tumour promoter in the medium.

These data suggest that TPA might act directly on the *ras* transformants, stimulating their growth and thereby allowing them to overcome the inhibitory effects of adjacent normal cells. Alternatively, the promoter might act indirectly, affecting the normal cells and reducing their ability to inhibit growth of the *ras* transformants. To distinguish between these possibilities, we infected cells with the *ras* or the *myc* virus and split them 2 days later into two groups, one being transferred to medium with G418 alone, the other to medium containing G418 plus TPA. In this way, all adjacent normal cells were killed off, and the oncogene-bearing cells could grow up into isolated colonies.

As is clear from Fig. 3, within 1 week after plating, there was a strong effect of TPA on the size, but not the number, of '*ras* cell' colonies in a culture dish. When cells were trypsinized and counted, 10 times more cells were found in the presence of TPA than in its absence. No such difference could be detected in either the control cells or the *myc*-bearing cells. We conclude that at least part of the synergism between TPA and the *ras* oncogene derives from direct effects on the *ras*-bearing cells. While TPA might be able to affect adjacent normal cells, such effects do not need to be invoked to explain our results.

Initiated cells *in vivo* are induced to grow out into papillomas by the continued application of TPA^{1,5,6} and this effect can be blocked by the concomitant application of retinoic acid¹³. As Table 1 shows, retinoic acid exerts an analogous activity in our system, in that it can effectively block the TPA-dependent outgrowth of '*ras*' foci. Thus, TPA and retinoic acid seem to interact similarly *in vivo*, in the promotion and repression of papilloma formation, and *in vitro*, in the stimulation and suppression of growth of *ras*-transformed cells.

Promotion of papillomas can be resolved into two steps^{14,15}. First-stage promotion can be brought about by a single application of TPA, while second-stage promotion requires prolonged applications of either TPA or 'second-stage promoters', such as 12-*O*-retinoylphorbol-13-acetate (RPA) or mezerein, which are either not active or very weakly active in the first stage^{14,15}. These compounds, when tested in our system, were found to be about

Table 1 Effects of various chemicals on focus formation of REFs bearing *ras* oncogene

Chemical	Number of foci per dish
—	0
TPA (10 ng ml^{-1})	55
TPA + RA ($10 \mu\text{M}$)	0
TPA + RA ($1 \mu\text{M}$)	0
TPA + RA ($0.1 \mu\text{M}$)	5
TPA + RA ($0.01 \mu\text{M}$)	45
RPA (100 ng ml^{-1})	60
RPA (10 ng ml^{-1})	40
Mezerein (100 ng ml^{-1})	45
Mezerein (10 ng ml^{-1})	10
4 α -PDD (100 ng ml^{-1})	0
4 α -PDD (10 ng ml^{-1})	0

REFs were infected as described in Fig. 1 legend and after 48 h re-plated (1:10 split) into either normal medium or medium containing the various chemicals; 10 days later, the dishes were stained and foci counted. Two independent dishes were counted for each value shown. TPA and retinoic acid (RA) were purchased from Sigma; RPA, mezerein and 4 α -PDD from LC Services Corp., Woburn, Massachusetts.

as active as TPA (Table 1); this suggests that introduction of an activated *ras* oncogene might bypass the requirements for first-stage promotion and allow these cells to respond directly to second-stage promoters. Another phorbol ester derivative, 4 α -phorbol-12,13-didecanoate (4 α -PDD), which has been shown previously to be inactive both *in vivo* and *in vitro*¹⁶, was also tested in our system and found to have no activity (Table 1).

Activated *ras* and *myc* oncogenes have been found in a large variety of tumours, both of spontaneous origin and chemically induced, and it is assumed that activation of these genes has a causal role in tumour development¹⁷. The present work provides a direct and quantitative demonstration that introduction of an activated *ras*—but not *myc*—oncogene into primary cells causes these cells to respond to a promoter in the manner of an initiated cell. This provides an *in vitro* parallel with work from other laboratories which suggests that *ras* activation occurs at very early times during initiation/promotion of carcinogenesis *in vivo* and may even coincide with the initiating event^{18–21}.

Others have recently reported that TPA is able to act synergistically with *myc*²². This observation is only in apparent contrast to ours as these workers used TPA concentrations that were 1,000-fold higher than those used in the present study and they

detected foci of *myc* transfectants in immortalized cells in the presence of TPA only after 6 weeks, in contrast to the 1-week lag period reported here.

TPA, like the *myc* oncogene, is able to collaborate with a *ras* oncogene to allow focal overgrowth in monolayer culture. In this limited sense, TPA acts analogously to *myc*, achieving epigenetically the same effects as those of a genetically activated *myc* gene. We note that TPA has been found to induce expression of the normal cellular *myc* gene²³. This induction may represent the mechanistic basis by which TPA is able to mimic *myc* in the present experimental model.

We thank Midori Maruyama for technical help and Bernard Mathey-Prevot for critical reading of the manuscript. This project was supported by grant CA 39963 from the US NCI and by a grant from the American Business Cancer Research Fund. C_{μ} -containing transcripts initiate heterogeneously within the *IgH* enhancer region and contain a novel 5'-nontranslatable exon

Gregory G. Lennon & Robert P. Perry

Institute for Cancer Research, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111, USA

Transcriptional competence of the immunoglobulin heavy-chain locus (*IgH*) is established at an early stage of lymphoid cell development, leading to the appearance of RNA components, previously called C_{μ} RNA¹ or sterile- μ RNA², which contain constant-region sequences but lack variable-region sequences. These components are of two types: those which initiate in the *D* region of alleles that have undergone *DJ_H* (diversity-joining region) rearrangement (D_{μ} transcripts) and those which initiate within the *J_H-C_μ* intron (hereafter termed I_{μ} transcripts)^{3,4}. In pre-B and early B cells, D_{μ} and I_{μ} transcripts are nearly as abundant as the messenger RNA encoding μ heavy chain^{2,3,5}. The D_{μ} transcripts are spliced into RNAs containing *D*, *J_H* and C_{μ} sequences, and in some, but not all, cases these RNAs are translated into D_{μ} proteins⁴. To establish whether the I_{μ} transcripts have any translational potential and to elucidate the structure of their promoter region, we have determined their transcription initiation sites and their mode of splicing. As reported here, by using sequence

Fig. 1 Schematic diagram of mouse immunoglobulin heavy chain genes and relevant probes. The germline (H^+) region that is common to both alleles of the lymphoma 38C-13 (ref. 3) is shown in the middle of the figure. The upper expansion of the enhancer (E) region shows the location of the octanucleotide (O_8) oriented as in V_{κ} genes. The box to the left of PE (primer extension) indicates the binding position of the 21-mer oligonucleotide. The *PvuII-EcoRI* S_1 probe was isolated from an *Sp6* subclone containing a 700-base pair (bp) *XbaI-EcoRI* insert. The lower expansion shows the 5' region of the productive allele. The *EcoRI-AhaIII* S_1 probe was isolated from subclone p38CV which contains the *IcoRI-BamHI* insert shown. Abbreviations of restriction sites: P, *PvuII*; R, *EcoRI*; B, *BamHI*; A, *AhaIII*. (Not all sites are shown.)

analysis of cloned I_{μ} complementary DNAs, primer extension and S_1 nuclease mapping, we have found that these transcripts have remarkable 5' heterogeneity: there are more than five distinct start sites spanning a region of 44 nucleotides that is located downstream of an octanucleotide found in all variable-region promoters. Such imprecise initiation may result from the lack of a well-defined TATAA motif and the unusual proximity of the octanucleotide to the enhancer region. Approximately 700 nucleotides downstream from these initiation sites, a cryptic splice site is used to create a nontranslatable exon ('nontron') which is joined to the C_{μ} domain. The properties of the nontron may be important for the mechanism of allelic exclusion.

Cloned cDNAs representative of I_{μ} transcripts were obtained from a λ gt10 cDNA library made from RNA of the mouse lymphoma 38C-13. This lymphoma contains cytoplasmic I_{μ} RNA components, presumably transcribed from both productive (H^+) and nonproductive (H^-) alleles, which can be readily distinguished from the mRNA encoding the complete μ heavy chain by their ability to hybridize with a probe specific for a 5' portion of the *J_H-C_μ* intron³. On screening the library with such a probe (IVS₁, ref. 3), we obtained 12 positive clones out of approximately 6×10^5 plaques. The two longest cDNA inserts were purified, subcloned into pUC plasmids, and sequenced. The sequence of their 5' ends mapped within the 0.32-kilobase (kb) *PvuII-EcoRI* fragment previously shown to contain the 5' boundary of some of the C_{μ} RNA components¹ as well as the heavy-chain enhancer element^{6,7}.

To localize precisely the sites at which the I_{μ} transcripts initiate, we used both primer extension and S_1 nuclease mapping (Fig. 1). For primer extension of 38C-13 cytoplasmic RNA, we used a 21-mer oligonucleotide representing a sequence near the 3' boundary of the enhancer region. Several products extending 37-80 nucleotides upstream of the primer were observed (Fig. 2a), suggesting the existence of either a multiplicity of transcriptional start sites or a series of reverse transcriptase-dependent artefactual stop sites. S_1 nuclease analysis using a single-stranded *PvuII-EcoRI* fragment allowed us to distinguish between these two possibilities. As a control, we simultaneously determined the start site of the 38C-13 μ mRNA, using the same RNA preparation and an *EcoRI-AhaIII* fragment spanning the leader exon of the productive H^+ gene (Fig. 1). The results of this analysis were clear-cut: the μ mRNA initiates at a unique site (Fig. 2c, lanes 3, 4), whereas the initiation sites of the I_{μ} transcripts are indeed heterogeneous (Fig. 2b, lane 2), corresponding exactly to those seen by the primer extension assay. A similar result was obtained with RNA from C2 cells, a

Fig. 2 Mapping of transcription initiation sites. **a**, Primer extension. 50 ng of 21-mer labelled with [γ -³²P]dATP was hybridized to 10 µg of 38C cytoplasmic poly(A)⁺ RNA for 33 h at 37 °C in 20 µl of a solution containing 80% formamide³¹ and 21 µg of poly(A)⁺ cytoplasmic carrier RNA obtained from MPC 11 myeloma cells. Most of the unannealed primer was removed by oligo(dT)-cellulose chromatography, and the remaining material extended using avian myeloblastosis virus reverse transcriptase. Products were loaded onto a 10% polyacrylamide/7 M urea thickness-gradient gel. Numbering indicates the distance (in nucleotides) downstream from the first nucleotide of the conserved octanucleotide. The strong band at the bottom is non-extended primer. **b**, S₁ protection assay of *I*_μ transcripts. RNA samples were annealed to a gel-separated minus-strand probe (upper expansion, Fig. 1) for 3 h at 40 °C, then the samples were diluted and treated for 37 min at 19 °C with 4,000 units of S₁ nuclease³². Lane 1, 20 µg C2 cytoplasmic poly(A)⁺ RNA; lane 2, 20 µg 38C cytoplasmic poly(A)⁺ RNA; lanes 3, 4, no RNA (S₁ nuclease treatment omitted for lane 3). **c**, S₁ protection assay of *H*⁺ transcripts. Same general protocol as for **b**. The minus-strand probe is shown in the lower extension of Fig. 1. Lanes 1 and 2, 1 and 5 µg of carrier RNA, respectively (S₁ nuclease treatment omitted for lane 1); lane 3, 1 µg 38C cytoplasmic poly(A)⁺ RNA; lane 4, 5 µg 38C cytoplasmic poly(A)⁺ RNA. M, G + A sequencing reactions of the appropriate probe plus strands, one of the three such sequencing reactions used as markers. Transcription initiation sites were determined from a comparison of S₁ nuclease-resistant fragments and marker lanes, applying the 4.5-nucleotide correction factor established in previous experiments³³.

hybridoma derivative of 38C-13 which contains only the nonproductive (*H*⁻) allele³ (Fig. 2b, lane 1). There appears to be a difference in the relative abundance of the various fragments protected by 38C and C2 RNA, suggesting a possible difference in the relative utilization of the different *I*_μ start sites in these two cells. Whether this difference is related to a difference in *I*_μ transcription on the *H*⁺ and *H*⁻ alleles remains to be established.

The *I*_μ start sites are located (Fig. 3a) 43–86 nucleotides downstream of a highly conserved^{8,9} octanucleotide (ATTTGCAT) which is found in all *V*_κ genes and, in inverse orientation, in all *V*_H genes about 60–80 nucleotides upstream of the cap site. This octanucleotide element is apparently essential for the transcriptional activity of these genes^{9,10}. *In vivo* footprinting assays¹¹ have indicated that almost all tissue-specific protein binding in the enhancer region occurs upstream of this octanucleotide (Fig. 3a), suggesting that this region may contain binding sites for factors that are important for the generation of *I*_μ transcripts. Comparing the position of the octanucleotide implicated in *I*_μ transcription with that of an octanucleotide brought upstream of the enhancer by the productive rearrangement of a *V*_H gene, we note that the *I*_μ octanucleotide is located on the opposite side of these binding sites and in inverse orientation. Thus, the polarity relative to the binding sites is the same for both *I*_μ and *H*⁺ octanucleotides.

The 38C *H*⁺ gene promoter has a TATAA box correctly spaced upstream of the unique initiation site (Fig. 3b), whereas for the *I*_μ transcripts there is no unique, well-defined TATAA box. Initiation heterogeneity similar to that observed for *I*_μ transcription has been observed at sites adjacent to the simian virus 40 (SV40) and polyoma enhancers^{12,13}. The viral promoters responsible for these transcripts also lack TATAA box homologies. To date, very few cellular genes with this extent of

heterogeneity have been described, although one interesting exception is the hydroxymethyl glutaryl coenzyme A reductase gene, which initiates heterogeneously in a G + C-rich region that lacks a TATAA box¹⁴. However, as several other genes, including even some *V*_H and *V*_κ genes, can initiate precisely despite the lack of a good TATAA motif (see refs 15 and 16 for examples), it is clear that the absence of this motif does not necessarily engender transcriptional heterogeneity. Perhaps the unusual proximity of the octanucleotide to the major protein-binding region of the enhancer also contributes to the imprecise initiation of *I*_μ transcripts.

Knowledge of the cDNA sequences allowed us to identify the 5' splice site used in the processing of the *I*_μ transcripts. The junction between the *J*_H-*C*_μ intron sequence and the *C*_μ1 exon is the same in both cDNA sequences; it defines a splice site 735 nucleotides downstream from the most 5' of the transcriptional start sites (Fig. 3c). The sequences flanking this splice site, which is normally not recognized in the splicing of pre-*μ* mRNA or *D*_μ transcripts, conform reasonably well to the consensus for 5' splice sites¹⁷. Utilization of this cryptic splice site creates a large exon that contains over 35 termination codons in the three reading frames (Fig. 4). Indeed, in the frame that encodes the *C*_μ protein, there are more than 10 stop codons distributed over the entire exon segment, and utilization of the first non-blocked initiation codon would eliminate 25 amino acids from the *C*_μ1 domain. Moreover, according to present ideas about translation initiation¹⁸, such an exceptionally long nontranslatable 5' exon (nontron), with at least 12 AUG codons, should greatly reduce the efficiency with which *I*_μ transcripts can be translated into any protein with *C*_μ determinants. Thus, it is now evident why such proteins are not detected in cells that are demonstrably producing *I*_μ transcripts¹⁹.

A matrix-plot comparison of the mouse and human *J*_H-*C*_μ intron sequences revealed a remarkable (for intron sequences) conservation of the 5' portion of this intron²⁰. The conserved segment not only embraces the enhancer region, including a 7/8 octanucleotide homologue, but in fact extends slightly beyond the 3' border of the nontron and includes its splice junction and over 40 stop codons. The fact that both the cryptic splice site and the multiplicity of stop codons are evolutionarily conserved suggests that the nontron may be of functional significance. What could be the significance of an element that prevents *C*_μ translation? One possibility which we find attractive is related to mechanistic models of allelic exclusion^{21–23}. An important attribute of these models is a feedback system which causes the

Fig. 3 Sequence characteristics of I_μ transcripts. *a*, A 298-nucleotide sequence of the *IgH* enhancer region (as listed in GenBank and confirmed by us) showing the transcription initiation sites (*). The *PvuII* site corresponds to that shown in Fig. 1. The octanucleotide is boxed; ▼ indicates the nucleotide where the longest cDNA begins; ○ and ●, respectively, indicate protection from, and enhancement of, reactivity with dimethyl sulphate by lymphocyte-specific factors¹¹. *b*, Sequence of the 5' region of the 38C H^+ gene (downstream of the *EcoRI* site, determined by chemical cleavage; upstream, taken from the sequence³³ of a closely related gene, V_{H11}) showing the initiation site (*), as well as the octanucleotide and TATAA motifs (boxed). Horizontal arrows under the octanucleotides emphasize the inverted polarity of these sequences in I_μ and V_H promoters. *c*, Sequence spanning the site (/) at which the 5' portion of the I_μ transcript is spliced to the C_μ exon, as determined from the cDNA sequence. The sequence of this region agrees with that listed in GenBank.

Fig. 4 Schematic diagram of the processed portions of I_μ transcripts. N, nontron; E, enhancer region; ↓↓, initiation sites; C_μ , entire C_μ region, which is joined to either a secretory (μ_S) or a membrane-associated (μ_M) polyadenylated terminus. Reading frames are aligned according to the splice junction shown in Fig. 3c. ▲, Location of AUG codons in the nontron (the first AUG in the C_μ coding frame is also indicated); vertical bars represent stop codons.

developing B lymphocyte to cease rearranging its immunoglobulin genes when a productive rearrangement has been made. There are two stages at which the cell apparently recognizes such feedback signals: first, when a heavy-chain gene has been productively rearranged, and later when a productive light-chain rearrangement occurs. While the second signal could be related to the appearance of a completely assembled immunoglobulin on the cell surface, the first would presumably result from the appearance of intracellular μ heavy chain. If the C_μ region were the critical determinant for this feedback signal, then any translation products of the I_μ transcripts could repress the rearrangement of heavy-chain genes prior to the formation of a productive allele. Thus, we propose that the nontron prevents the generation of a feedback signal which would prematurely curtail heavy-chain gene rearrangement. We are implicitly assuming here that early transcriptional activity at the heavy-chain locus is essential for, or at least an obligatory concomitant of, the rearrangement mechanism. The fact that C_κ (refs 24, 25), V_λ (ref. 26) and some V_H (ref. 27) regions are transcriptionally active prior to rearrangement lends support to this notion.

If our proposal is correct and any C_μ -containing polypeptide can serve as a feedback signal, we must presume that the so-called D_μ proteins, which are produced when the 5'-flanking regions of certain D elements are joined in the proper reading frame to a J element, would also inhibit further rearrangement. Although examples of Abelson virus-transformed pre-B-cell lines that produce D_μ proteins and are still capable of undergoing VD rearrangement have been reported⁴, more recent findings²⁸ indicate that such rearrangement occurs only when the level of D_μ protein is very low, and that high levels of D_μ protein may, in fact, be inhibitory for recombination. The I_μ RNAs are more abundant than D_μ RNA (ref. 3 and our unpublished observations) and are generated over a longer time span since their production is independent of the rearrangement status of the H alleles. Hence, if there were translation products of I_μ RNAs, they would probably be at sufficiently high con-

centrations to repress recombination. We also find it noteworthy that for most H^+ loci in which the D segment can be unambiguously identified, the $D-J$ join is in a frame that could not have previously produced a D_μ protein^{29,30}. Thus, there may actually be an inverse correlation between the ability to produce D_μ protein and the subsequent possession of a completely rearranged H allele.

Irrespective of its implications for allelic exclusion, the properties of the nontron may represent a means of accommodating a possible requirement for transcriptional competence at the J_H-C_μ locus while avoiding the deleterious consequences of a protein potentially encoded by the transcription product.

We thank Kathleen Nelson, Leanne Wiedemann and Michal Fried for helpful discussions, Tom St John and Irving Weissman for the 38C cDNA library, Michael Kriegler for the oligonucleotide primer, Mark Shlomchik for primer extension reagents, Dawn Kelley for the p38CV subclone, and Gerald Siu for the unpublished V_{H11} sequence. Resistance to β -lactam antibiotics by re-modelling the active site of an *E. coli* penicillin-binding protein

Philip J. Hedge & Brian G. Spratt

Microbial Genetics Group, School of Biological Sciences,
University of Sussex, Falmer, Brighton BN1 9QG, UK

The β -lactam antibiotics kill bacteria by inhibiting a set of penicillin-binding proteins (PBPs) that catalyse the final stages of peptidoglycan synthesis^{1,2}. In some bacteria the development of intrinsic resistance to β -lactam antibiotics by the reduction in the affinity of PBPs causes serious clinical problems^{1,3-11}. The introduction of β -lactam antibiotics that are resistant to hydrolysis by β -lactamases may also result in the emergence of intrinsic resistance among the Enterobacteriaceae¹. The clinical problems that would arise from the emergence of resistant PBPs in enterobacteria have led us to examine the ease with which *Escherichia coli* can gain resistance to β -lactams by the production of altered PBPs. The development of resistant PBPs also provides an interesting example of enzyme evolution, since it requires a subtle re-modelling of the enzyme active centre so that it retains affinity for its peptide substrate but excludes the structurally analogous^{2,12,13} β -lactam antibiotics. We show here that only four amino-acid substitutions need to be introduced into PBP 3 of *E. coli* to produce a strain possessing substantial levels of resistance to a wide variety of cephalosporins. We also show that transfer of the gene encoding the resistant PBP 3 from the chromosome to a plasmid could result in the spread of intrinsic resistance not only to other strains of *E. coli* but also to other enterobacterial species.

Most β -lactam antibiotics in clinical use kill *E. coli* at their minimum inhibitory concentrations by inactivation of PBP 3, resulting in the inhibition of cell division and the growth of the bacteria into filamentous cells^{1,14}. Many of these antibiotics (for example, cephalixin, cefuroxime, third-generation cephalosporins, mezlocillin, piperacillin and monobactams¹⁵) show much greater affinity for PBP 3 than for the other essential PBPs, and therefore kill *E. coli* over a wide concentration range exclusively by inactivation of PBP 3¹. Substantial levels of resistance to these β -lactams could therefore be achieved by the development of a form of PBP 3 that has reduced affinity for the antibiotics. Amino-acid substitutions that allow PBP 3 to discriminate between the binding of cephalixin and its normal substrate are, however, very rare and result in only a low level of resistance¹⁶. Mutants with high levels of resistance require multiple amino-acid substitutions in PBP 3 which re-model the active centre to reduce its affinity for β -lactams without impairing its ability to process the normal substrate. We have followed

Fig. 1 Affinity of PBP 3 of the fourth-level mutant (SP1124) for benzylpenicillin and cephalixin²⁶. Increasing concentrations of ³H-benzylpenicillin (21 Ci mmol⁻¹; a gift of Merck Sharp and Dohme) were incubated for 10 min at 30 °C with washed cell envelopes prepared from *E. coli* expressing wild-type PBP 3 (strain C600pPH105) (A) or the resistant PBP 3 of the fourth-generation mutant (strain SP1124pPH105pbpB^R) (B). The reactions were terminated and the PBPs fractionated on a 10% SDS polyacrylamide gel as described elsewhere²⁶. The levels of ³H-benzylpenicillin bound to the PBPs were determined by fluorography. Only the section of the fluorograph showing PBP 3 is illustrated. ³H-benzylpenicillin concentrations (μ g ml⁻¹): a, 0.06; b, 0.12; c, 0.25; d, 0.5; e, 1; f, 2; g, 4; h, 8; i, 16. A measure of the affinity of the PBPs for cephalixin was obtained by incubating washed cell envelopes of strain C600pPH105 (C) or SP1124pPH105pbpB^R (D) with increasing concentrations of cephalixin for 10 min at 30 °C and then adding ³H-benzylpenicillin (30 μ g ml⁻¹ final concentration) for a further 10 min to label the PBPs that are not complexed with cephalixin²⁶. The PBPs were separated and visualized as above. Only the section of the fluorograph showing PBP 3 is illustrated. Cephalixin concentrations (mg ml⁻¹): a, 0; b, 0.015; c, 0.03; d, 0.06; e, 0.12; f, 0.24; g, 0.47; h, 0.95; i, 1.9; j, 3.8; k, 7.5; l, 15; m and n, 30.

the evolution of *E. coli* PBP 3 during selection for increasing levels of resistance to cephalosporins.

The most resistant of the cephalixin-resistant mutants obtained in our previous study¹⁶ (SP1091; Table 1) was mutagenized separately with ethyl methane sulphonate, ultraviolet irradiation and nitroquinoline *N*-oxide, and second-level mutants showing increased levels of resistance to cephalixin were selected at 37 °C. Those mutants in which the increased resistance was due to a further reduction in the affinity of PBP 3 for cephalixin were distinguished from the majority of the mutants in which resistance was due to decreased outer membrane permeability¹⁷ or increased expression of the chromosomal β -lactamase¹⁸, by the phage P1-mediated co-transduction of the resistance with the *leu* genes which map very close to the PBP 3 gene (*pbpB*)¹⁹. However, second-level PBP 3 mutants that showed a substantial increase in resistance could not be obtained from any of the mutagenized cultures and the best mutants obtained showed only a slight increase in cephalixin resistance. The decrease in the affinity of PBP 3 for cephalixin in SP1091 resulted in a decrease in its thermostability so that the strain grew well at 37 °C but filamented and died at 43 °C¹⁶. The second-level mutants had regained the normal thermostability of PBP 3 and the ability to form colonies at 43 °C.

One of the second-level mutants (SP1096, a transductant carrying the mutant *pbpB* gene in an unmutagenized background) was treated with each of the mutagens and selection was applied for a further increase in cephalixin resistance; those third-level mutants in which the increased resistance was due to PBP 3 changes were identified. Repeated attempts to obtain third-level mutants produced only one isolate (SP1097), which showed a further substantial increase in PBP 3-mediated cephalixin resistance. The decrease in affinity of PBP 3 of SP1097 was accompanied by decreased thermostability and the

Table 1 Properties of a series of PBP 3 mutants with increasing levels of resistance to cephalosporins

Strain	Minimum inhibitory concentration ($\mu\text{g ml}^{-1}$) of														Growth at 43 °C
	Clxn	Cdrx	Crln	Cthn	Crxm	Cmdl	Ctxm	Ctaz	Cprz	Ampn	Pipn	Mzln	Ticn	Aztr	
C600 (parent)	6	10	20	5	5	1	0.1	0.2	0.2	5	2	2	5	0.1	Yes
SP1091 (first level)	50	100	200	100	100	2	0.1	0.1	0.1	1	0.5	0.5	0.5	0.05	No
SP1096 (second level)	60	100	100	20	10	5	0.1	0.1	0.5	10	2	2	1	0.1	Yes
SP1097 (third level)	500	400	1,000	200	200	40	1	1	0.5	5	1	1	1	0.05	No
SP1124 (fourth level)	500	400	2,000	200	500	40	2	2	1	5	5	2	2	0.1	Yes

The isolation of the first-level mutant, SP1091, and the methods for identifying *pbpB* mutants, have been described elsewhere¹⁶. The mutants with increasing levels of resistance to cephalosporins were isolated after mutagenesis with ethyl methane sulphonate²⁰, ultraviolet irradiation²¹ or nitroquinoline *N*-oxide²¹ as described in the text. Determination of minimal inhibitory concentrations: 10- μl amounts of a 10^{-5} dilution of overnight cultures of the mutants and the parent strain (~ 150 colony-forming units) were spotted on L-agar containing a range of concentrations of the antibiotics. The plates were incubated at 37 °C for 24 h and the minimum inhibitory concentration was the lowest concentration of antibiotic that prevented bacterial growth. A similar number of cells were plated on L-agar at 43 °C to test the ability of the mutants to grow at this temperature. Abbreviations for cephalosporins: Clxn, cephalixin; Cdrx, cefadroxil; Crln, cephradine; Cthn, cephalothin; Crxm, cefuroxime; Cmdl, cefamandole; Ctxm, cefotaxime; Ctaz, ceftazidime; Cprz, cefoperazone. Abbreviations for penicillins: Ampn, ampicillin; Pipn, piperacillin; Mzln, mezlocillin; Ticn, ticarcillin. Aztr is aztreonam, a monobactam¹⁵.

Table 2 Nucleotide changes in the *pbpB* gene, and the predicted amino-acid substitutions in PBP 3, of a series of mutants showing increasing levels of resistance to cephalosporins

Strain	Mutagen used for isolation	Nucleotide change in <i>pbpB</i>	Amino-acid substitution in PBP 3
SP1091 (first level)	Ethyl methane sulphonate	AAC to AGC	Asn 361 to Ser
SP1096 (second level)	Ethyl methane sulphonate	GTT to ATT	Val 530 to Ile
SP1097 (third level)	Ultraviolet irradiation	TAC to CTC	Tyr 541 to Leu
SP1124 (fourth level)	Ethyl methane sulphonate	GAA to AAA	Glu 349 to Lys

The wild-type *pbpB* gene was cloned into the pSC101-derived vector, pLG339, to produce pPH105²². The mutations in the *pbpB* gene of each of the mutants were transferred into pPH105 *in vivo* by homogenization as described previously¹⁶. The wild-type and mutant *pbpB* genes were cloned from these plasmids into phage M13 mp8/9 vectors²³ and were dideoxy-sequenced²⁴ on both strands using a set of oligonucleotide primers complementary to regions along each strand of the *pbpB* gene as described previously¹⁶. The nucleotide sequence of the wild-type *pbpB* gene has been determined by Nakamura *et al.*²⁵. The nucleotide changes shown are the new mutations that have occurred at each level; in addition, the *pbpB* gene of the mutants contained the mutations they obtained at the earlier levels.

Table 3 Conferral of cephalosporin resistance on enterobacteria by the introduction of a plasmid expressing a cephalosporin-resistant form of PBP 3

Strain	Minimum inhibitory concentrations ($\mu\text{g ml}^{-1}$) of:						
	Clxn	Crln	Cthn	Crxm	Cmdl	Ctxm	Cprz
<i>E. coli</i> pPH105	6	20	5	5	1	0.1	0.2
<i>E. coli</i> pPH105 <i>pbpB</i> ^{rs}	500	2,000	200	500	50	2	1
<i>S. typhimurium</i> pPH105	5	20	1	2	<0.2	0.1	0.5
<i>S. typhimurium</i> pPH105 <i>pbpB</i> ^{rs}	500	500	20	100	5	0.5	2
<i>K. pneumoniae</i> pPH105	5	10	2	2	0.5	0.05	0.5
<i>K. pneumoniae</i> pPH105 <i>pbpB</i> ^{rs}	500	1,000	50	100	50	0.5	5

pPH105, expressing wild-type PBP 3, and pPH105*pbpB*^{rs}, expressing the resistant PBP 3 of the fourth-level mutant SP1124, were introduced by transformation into *E. coli* C600, *S. typhimurium* LR5000 and *Klebsiella pneumoniae* UNF122. The abbreviations for antibiotics and the method for measuring the minimum inhibitory concentrations are as in Table 1.

strain filamented at 43 °C. The increased resistance of strain SP1097 was due to a double nucleotide change in *pbpB* (Table 2). Presumably SP1097 was obtained at such a low frequency because there were no single-nucleotide changes in the *pbpB* gene of the second-level mutant that produced the desired phenotype.

SP1097 lysed when grown in the presence of its minimum inhibitory concentration of cephalixin, indicating that the affinity of PBP 3 had been reduced to the extent that killing was now occurring by the inactivation of PBP 1A/1B rather than PBP 3. The mutant had therefore achieved the maximum level of resistance to cephalixin that could be achieved by a reduction in the affinity of PBP 3 and had also gained close to the maximum possible levels of cross-resistance to a number of other cephalo-

sporins (such as cefadroxil, cephradine, cefuroxime and cephalothin). The mutant had, however, not achieved the maximum possible levels of resistance to third-generation cephalosporins and further attempts to re-model the active site of PBP 3 to give resistance to all of those cephalosporins that kill by inactivation of PBP 3 were carried out by selecting for increased resistance to cefoperazone, ceftazidime and cefotaxime. The fourth-level mutants obtained by selecting for resistance to the above compounds had only a slight further increase in their resistance to cephalosporins and had simultaneously regained the ability to form colonies at 43 °C. Attempts to produce fifth-level mutants by selecting for additional resistance to third-generation cephalosporins have been unsuccessful.

The properties of the series of mutants are shown in Table 1, while Table 2 shows the nucleotide substitutions that have occurred in the *pbpB* gene at each level of selection. Interestingly, the evolution of PBP 3 in this series of mutants has occurred by amino-acid substitutions that alternately reduce the affinity of the enzyme for cephalosporins but de-stabilize the enzyme, and those that have little or no effect on affinity but which re-stabilize the enzyme.

The fourth-level mutant (SP1124) showed the maximum levels of resistance to almost all cephalosporins that can be achieved by reduction of the affinity of PBP 3 (Table 1). The increase in resistance that has been gained in the latter mutant by four amino-acid substitutions in PBP 3 would probably be sufficient to prevent successful therapy by most cephalosporins.

SP1124 showed cross-resistance to those cephalosporins that kill by inactivation of PBP 3 but not to any of the penicillins or monobactams that were tested. As expected, the affinity of strain SP1124 PBP 3 for benzylpenicillin was only slightly reduced from that of the parent strain (C600), whereas its affinity for cephalixin was greatly reduced (Fig. 1). It might be expected, *a priori*, that penicillins, monobactams and cephalosporins would have a substantial degree of overlap in their binding sites on the enzyme and it is surprising that the re-modelling of PBP 3 to reduce its affinity for cephalosporins has had no apparent effect on the binding of the penicillins or monobactams. This suggests that there may, in fact, be little overlap between the binding sites for cephalosporins and the other classes of β -lactam antibiotics. Further evolution of the active site of PBP 3 to exclude penicillins and monobactams as well as cephalosporins could probably be achieved, but we have not attempted to do this for safety reasons.

A plasmid that expressed the *pbpB* gene of the fourth-level mutant could transform a sensitive strain of *E. coli*, *Salmonella typhimurium* or *Klebsiella pneumoniae* to broad-spectrum cephalosporin resistance (Table 3). If resistant forms of PBP 3 evolve in clinical isolates, the transfer of the altered PBP gene to a plasmid could therefore result in the infectious spread of resistance through *E. coli* and other species of the Enterobacteriaceae. The consequences of such events for the treatment of enterobacterial infections with β -lactam antibiotics would be considerable.

P.J.H. was in receipt of an MRC Biotechnology Studentship. We thank Dr J. K. Broome-Smith for helpful comments on the manuscript, Glaxo Group Research for oligonucleotides and Dr P. J. Cassidy of Merck Sharp and Dohme for ^3H -benzylpenicillin.

The immunodominant site of a synthetic immunogen has a conformational preference in water for a type-II reverse turn

H. Jane Dyson, Keith J. Cross, Richard A. Houghten, Ian A. Wilson, Peter E. Wright & Richard A. Lerner

Department of Molecular Biology, Research Institute of Scripps Clinic, La Jolla, California 92037, USA

Many short synthetic peptides have now been shown to induce antibodies reactive with their cognate sequences in the intact folded protein¹⁻³. Aside from the usefulness of such antibodies as site-specific reagents, the frequency with which this recognition occurs has raised several theoretical issues, the central one being that of how an antibody to a short synthetic peptide, which represents one of the most disordered states of a site in a protein, can react with the more ordered version of the same sequence in the folded protein. This apparent paradox can be resolved if the target site on the protein approaches disorder or if the peptide in solution or on a carrier adopts, with significant frequency, a conformation compatible with that of the cognate site in the protein. Various studies already suggest that antigenic sites in proteins correspond to regions of high atomic mobility^{1,9-15}. We now show, using high-field nuclear magnetic resonance (NMR) spectroscopy, that a nonapeptide selected by several monoclonal antibodies as the immunodominant site of a 36-amino-acid immunogen (residues 75-110 of influenza virus haemagglutinin^{16,17}) adopts a highly populated type-II reverse-turn conformation in water. This suggests that in this case the antibodies have selected a sequence possessing a conformational preference. Apart from helping us to understand immunological recognition, anti-peptide antibodies may provide reagents of sufficient precision for an immunological approach to the problem of protein folding¹⁸⁻²³.

^1H -NMR spectroscopy provides a powerful method for determining molecular conformation in solution. In the present work, resonances were assigned to specific protons in the peptide using a combination of one- and two-dimensional methods. The conformation of the molecule was then examined by measuring nuclear Overhauser effects (NOEs), coupling constants and temperature and pH dependence of the NMR spectrum. The assignment procedure is illustrated in Fig. 1, which shows part of a two-dimensional scalar-correlated (COSY)²⁴⁻²⁶ spectrum. The cross-peaks establish unambiguously the coupling patterns (connectivities) for the resonances of each type of amino acid. Assignment to specific amino acids was based primarily on the observation of NOEs between resonances of sequentially adjacent amino acids. A detailed description of the assignments will be given elsewhere.

The NMR spectra of the peptide Tyr-Pro-Tyr-Asp-Val-Pro-Asp-Tyr-Ala are complicated by *cis-trans* isomerism²⁷ about the Tyr 1-Pro 2 peptide bond. This results in two distinct forms of the peptide which interconvert slowly on the NMR timescale. The relative intensities of peaks in the spectrum show that the two isomeric forms are present in the approximate *trans:cis* ratio of 2:1. This ratio appears to be little influenced by pH changes. Only the *trans* form appears to have demonstrable structure in water solution and thus is the subject of most of the following discussion.

The resonances of the exchangeable amide protons are absent from spectra of the peptide in D_2O . In H_2O , 12 amide proton resonances are observed, 6 from the *trans* and 6 from the *cis* form of the peptide (no NH proton resonances are expected for the N-terminal tyrosine or, of course, for the two prolines). The NH proton resonances were assigned from a COSY spectrum of the peptide in water solution (Fig. 2). Table 1 lists the assignments of the αCH and NH proton resonances. Unambiguous assignment of the aspartic acid spin systems is of

Fig. 1 a, Portion of the 500-MHz ^1H -NMR spectrum of haemagglutinin peptide (YPYDVDPYA) at 278 K. All spectra were recorded using a Bruker AM500 spectrometer. Dioxan (d) was used as an internal standard, but the spectrum is referenced to TSS at 0 parts per 10^6 (p.p.m.). pH values in D_2O solution refer to uncorrected meter readings. Peptide concentration ~ 10 mM in D_2O , adjusted to pH 4.15 with 0.1 M NaOD and 0.1 M DCl solutions in D_2O . The residual HOD peak was suppressed by gated irradiation. Resolution was enhanced by lorentzian-to-gaussian weighting. **b**, Portion of the aliphatic region of a phase-sensitive, double quantum filtered COSY spectrum²⁶ of peptide. The spectrum was obtained at 278 K using the same solution as that used to obtain the spectrum in **a**. The residual HOD resonance was suppressed by gated irradiation for 2 s before acquisition. A total of 512 points were acquired in the t_1 domain, with 16×2 K free induction decays acquired for each t_1 value. The spectrum was Fourier transformed in both dimensions using a phase-shifted sine bell window function (shifted $\pi/4$ in t_1 and $\pi/8$ in t_2). Connectivities for the proline residues (P2 and P6) and the aspartate residues (D4 and D7), and the α - β connectivities for valine (V5) and tyrosine (Y1, Y3 and Y8) are indicated for the *trans* form only. All other cross-peaks arise from resonances of the *cis* form. **Methods.** The peptide was synthesized on a Bioscience Sam Two peptide synthesizer and purified by HPLC as reported previously³⁵. The sequence of the peptide corresponds to residues 98–106 of the HA1 chain of the H3 subtype X:47 (A/Victoria/3/75) haemagglutinin¹⁶. The immunological properties of this peptide have been studied in detail¹⁶. The affinity of the monoclonal anti-peptide antibodies for the peptide is in the range 1.6×10^5 – 3.5×10^6 M^{-1} and for the haemagglutinin monomer 8×10^5 – 4×10^6 M^{-1} (K. Bergmann, T. Klinger and I.A.W., unpublished observations).

particular importance. Assignments were therefore made by isotopic substitution; a peptide was synthesized in which the amide N of Asp 4 was substituted with $>90\%$ ^{15}N . This nucleus has spin $1/2$ and causes splitting of the resonance of the attached proton. The spectrum of the ^{15}N -substituted peptide (Fig. 3b) allowed unequivocal assignment of the Asp 4 and Asp 7 proton resonances (both *trans* and *cis* forms).

Several NMR parameters provide information on molecular conformation. The temperature dependence of amide proton resonances can be used to identify backbone hydrogen bonding. Except for Asp 4 (*trans* form), the NH proton resonances show the characteristic temperature dependence expected for random-coil peptides, where amide protons are completely exposed to solvent (Table 2). The temperature coefficients of amide proton resonances are expected to be -6 to -10 parts per 10^9 (p.p.b.) per K for random-coil peptides in H_2O (ref. 28). A value of -3.5 p.p.b. per K for Asp 4 NH indicates that this proton is protected from solvent to a considerable extent; it is also protected from solvent at low pH. Since its temperature coefficients are the same in all conditions studied, the *cis* form may be used in this system as an unfolded control. In the presence of 6 M urea, the temperature coefficient for the Asp 4 (*trans*) NH is close to that for the *cis* form (Table 2). We conclude that the *trans* form is unfolded in the presence of urea. In a small monomeric peptide, protection from solvent is probably due to

Table 1 Assignment of αCH and NH resonances of haemagglutinin peptide

		298 K		278 K	
		<i>trans</i>	<i>cis</i> *	<i>trans</i>	<i>cis</i> *
Tyr 1	αCH	4.44	3.506	4.442	3.493
Pro 2	αCH	4.44		4.441	
Tyr 3	αCH	4.575	4.669	4.534	4.668
	NH	7.788	8.191	7.992	8.365
Asp 4	αCH	4.624	4.60	4.607	
	NH	8.242	8.490	8.320	8.605
Val 5	αCH	4.365	4.383	4.333	4.361
	NH	7.937	7.896	8.117	8.188
Pro 6	αCH	4.284	4.313	4.259	4.291
Asp 7	αCH	4.57	4.57	4.523	
	NH	8.280	8.330	8.449	8.504
Tyr 8	αCH	4.55	4.57	4.560	
	NH	7.941	7.972	8.135	8.155
Ala 9	αCH	4.146	4.15	4.127	
	NH	7.898	7.928	8.038	8.052

Spectra obtained for 10 mM solutions of haemagglutinin peptide in D_2O (αCH resonances) and in 90% $\text{H}_2\text{O}/10\%$ D_2O (NH resonances). The pH of the solution in each case (uncorrected meter readings) was 4.10 ± 0.5 . Dioxan was used as internal standard.

* Due to spectral overlap and low intensity, not all of the resonances from the *cis* form of the peptide could be assigned.

Fig. 2 Portion of the COSY spectrum of haemagglutinin peptide in H_2O solution. The spectrum was obtained using an 8 mM solution of peptide in 5% D_2O /95% H_2O at pH 4.15 and 296 K. A two-dimensional modification of the 'Jump-Return' sequence was used³⁶. 331 time domain points were acquired in t_1 , with 96 free induction decays acquired at each t_1 value. The spectrum was Fourier transformed in both dimensions using a sine bell window function. Cross-peaks between αCH and amide proton resonances are indicated for the *trans* form of the peptide only.

intramolecular hydrogen-bond formation. Reduced temperature coefficients for amide proton resonances have been used frequently to infer the presence of β -turns in peptides^{28,29}. These structures are usually observed in non-aqueous solvents such as dimethyl sulphoxide. In the present case, the temperature dependence of the Asp 4 (*trans*) amide proton resonance suggests participation in an intramolecular hydrogen bond in water solution. We note that the chemical shifts of the amide proton resonances are independent of peptide concentration over the range 1–10 mM, so that interactions between peptide molecules can be effectively discounted.

The existence of a β -bend in the haemagglutinin nonapeptide in water solution is confirmed by measurements of the NOEs. In a reverse turn formed by residues Tyr 1, Pro 2, Tyr 3 and Asp 4, there would be a hydrogen bond between the carbonyl group of Tyr 1 and the Asp 4 NH. Type-I, -II and -III β -turns are possible. In each case a small NOE is expected between the amide proton resonances of residues ($i+2$)(Tyr 3) and ($i+3$)(Asp 4)³⁰. A 2% NOE on the Tyr 3 NH is observed when the Asp 4 NH is irradiated. An NOE of similar size is seen on Asp 4 NH when Tyr 3 NH is irradiated (Fig. 3c). Type-II turns can be distinguished from type-I and -III turns by the presence of a strong NOE between the resonance of the αCH proton of residue ($i+1$) and the resonance of the amide proton of residue ($i+2$)³⁰. In the present case, a small NOE was observed on the αCH proton resonance of Pro 2 on irradiation of the Tyr 3 NH resonance. This NOE could not be readily quantitated because of the proximity of the Pro-2 αCH resonance to the large H_2O peak. In the reverse experiment, in which the αCH resonance of the proline was irradiated, an unequivocal NOE (9%) on the Tyr 3 NH resonance was observed (Fig. 3d). We conclude that, in water solutions of the peptide, a substantial population of conformers contains a type-II turn between residues 1 and 4. The β -turn is found only in the *trans* isomer; there is no evidence for any reverse-turn formation in the minor *cis* isomeric form.

The statistical weights of the three major side-chain rotamers³¹ of each amino-acid residue in the *trans* form of the haemagglutinin nonapeptide were calculated using values of the $^3J_{\alpha H-\beta H}$ coupling constants obtained from computer simulations of the strongly coupled $C\alpha H-C\beta H_2$ fragments of the spin systems. The rotamer populations for Tyr 1 are of particular note: it

appears that the *gauche* rotamer g^+g^- is not significantly populated in the *trans* form of the peptide. The absence of the g^+g^- rotamer is entirely consistent with the presence of a high proportion of molecules containing the β -turn structure, since this conformation would force energetically unfavourable steric crowding between the atoms involved in the turn and the aromatic ring of Tyr 1. We therefore conclude that the β -turn occurs in a high proportion of the conformational states of the *trans* form of the peptide in water solution.

The stable reverse turn reported here is in a peptide which is the site selected by the immune system as the immunodominant region of a larger peptide antigen. This observation bears significantly on several fundamental issues, including the problem of protein folding. Stable local structures, which may be different from those in the final folded protein, can be recognized by antibodies, and have been postulated as initiation sites in folding^{18,19,22,23}. Also, on theoretical grounds, reverse turns have been suggested as intermediates in protein folding²⁰. The experimental observation described here may thus link the immunological and theoretical approaches to protein folding.

Table 2 Temperature coefficients (p.p.b. per K) for NH resonances of haemagglutinin peptide

	pH 4.18		pH 1.50		pH 5.88 +6 M urea	
	<i>trans</i>	<i>cis</i>	<i>trans</i>	<i>cis</i>	<i>trans</i>	<i>cis</i>
Tyr	—	—	—	—	—	—
Pro	—	—	—	—	—	—
Tyr	-9.7	-8.0	-9.1	-7.3	-10.2	-7.6
Asp	-3.5	-5.7	-4.3	-5.8	-5.6	-6.3
Val	-8.3	-9.3	-7.3	-9.0	-9.0	-9.3
Pro	—	—	—	—	—	—
Asp	-8.3	-8.6	-8.1	-8.4	-8.7	-8.9
Tyr	-9.0	-9.1	-9.8	-9.0	-8.3	-8.3
Ala	-6.7	-6.7	-6.8	-6.8	-8.0	-7.9

Temperature coefficients were calculated by a linear least-squares fit to up to 12 data points for each resonance. The temperature coefficients recorded at all pH values above 4 were very similar, as expected since there are no deprotonations in the molecule between pH 4 and neutral pH. This suggests that the structure probably persists at neutral pH.

Fig. 3 *a*, Amide proton region of ^1H -NMR spectrum of the haemagglutinin peptide (10 mM in 90% $\text{H}_2\text{O}/10\%$ D_2O , adjusted to pH 4.10 with 0.1 M NaOH and 0.1 M HCl). The spectrum was obtained at 278 K using the Jump-Return sequence³⁷. Resolution was enhanced by lorentzian-gaussian transformation. 2,400 transients were collected. *b*, Amide proton region of spectrum of the haemagglutinin peptide with Asp 4 >90% enriched with ^{15}N . The spectrum shows splitting of the Asp 4 (*cis*) and Asp 4 (*trans*) NH resonances due to $^1J_{\text{NH}}$ coupling. The ^{15}N - β -benzyl-L-aspartate and ^{15}N -*tert*-butoxycarbonyl- β -benzyl aspartate intermediates for the synthesis of this peptide were prepared from >90% L-aspartic- ^{15}N acid (MSD Isotopes) by standard procedures^{38,39}. Peptide concentration was ~2 mM in 90% $\text{H}_2\text{O}/10\%$ D_2O at pH 4.07 at 278 K. *c*, NOE difference spectrum with 1.5-s gated irradiation of Tyr 3 NH resonance at 7.99 p.p.m. Total numbers of transients accumulated, 1,234. The free induction decay was subjected to exponential multiplication before Fourier transformation. *d*, NOE difference spectrum with 1.5-s gated irradiation of Pro-2 αCH resonance at 4.44 p.p.m. Total number of transients accumulated, 952. Resolution was enhanced by lorentzian-gaussian transformation. For the NOE experiments, spectra with the decoupler on- and off-resonance were interleaved (8 transients of each) and stored on the disk.

The main immunological question raised by this work is whether the presence of a stable reverse turn in a synthetic immunogen in water is important for recognition of the cognate sequence in the folded protein. A related question involves the extent to which antibody binding influences the conformation of the protein and the peptide. Previous studies using anti-protein antibodies have suggested that interaction with the antibody may itself introduce order into a peptide^{22,23,32-34}. In the present situation, the conformation of the peptide in solution and the cognate site in the crystal structure of the protein are different, suggesting that one or both must be altered in the antibody-binding site. Since we are dealing with a monoclonal antibody, the most direct approach to answering such questions is to determine the conformation of the synthetic immunogen when bound to the antibody. These studies are in progress, using both crystallographic and NMR methodologies.

Pending results from these studies, we can state our current view of how the immunological issues can be resolved. It seems that there may be a complementarity between the view that the site in the protein to which antibody binds is mobile and the postulate that the immunogenic peptide may be partially

ordered. In keeping with the diversity of the immune system, we would not expect all anti-peptide antibodies to be the same. Sometimes the balance will be towards disorder in the protein whereas at other times more order in the immunogen will be required.

We thank Dr Mark Rance for help with the NMR experiments. John Ostresh for synthesis of the ^{15}N -peptide and Gail Donnan for technical assistance. We acknowledge financial support from NIH grant AI19499 (to R.A.L. and I.A.W.). This is publication MB-3969 from Scripps Clinic.

Note added in proof: NMR studies of a peptide corresponding to an antigenic region of myelin basic protein have now been reported⁴⁰.

Identification of kinesin in sea urchin eggs, and evidence for its localization in the mitotic spindle

J. M. Scholey, M. E. Porter, P. M. Grissom & J. R. McIntosh

Department of Molecular, Cellular and Developmental Biology, University of Colorado at Boulder, Campus Box 347, Boulder, Colorado 80309, USA

To understand the molecular basis of microtubule-associated motility during mitosis^{1,2}, the mechanochemical factors that generate the relevant motile force must be identified. Myosin, the ATPase that interacts with actin to produce the force for muscle contraction and other forms of cell motility³, is believed to be involved in cytokinesis but not in mitosis⁴⁻⁷. Dynein, the mechanochemical enzyme that drives microtubule sliding in eukaryotic cilia and flagella^{8,9}, has been identified in the cytoplasm of sea urchin eggs¹⁰⁻¹⁹, but the evidence that it is involved in

Fig. 1 Specific AMPPNP-dependent co-pelleting of the 134K polypeptide with unfertilized egg cytoplasmic microtubules. The figure shows gels of the supernatants (lanes 1, 3, 5) and pellets (lanes 2, 4, 6) obtained from different experiments. Lanes 1, 2, plus AMPPNP plus colchicine (to block microtubule assembly); lanes 3, 4, no additions; lanes 5, 6, plus AMPPNP. Note that the 134K protein is only recovered in pellet 6, containing AMPPNP but not colchicine. Control microtubule (lane 4) and 'AMPPNP' microtubule (lane 6) pellets were washed to yield the supernatants and pellets shown in lanes 7, 8 and 9, 10, respectively. These pellets were subsequently extracted with 5 mM Mg-ATP, yielding supernatants and pellets shown in lanes 11 and 12, and 13 and 14, respectively. Note that the putative cytoplasmic dynein heavy chain (Dyn.) and the 134K polypeptide remain bound to the AMPPNP-microtubules through the washing step, but are both partially extracted by ATP (lane 13). The rest of the MAPs were extracted from the control and AMPPNP microtubules by differential centrifugation in 0.5 M NaCl plus 0.1 mM ATP; the corresponding supernatant and pellets are shown in lanes 15 and 16 and 17 and 18, respectively. Lane 19 is sea urchin sperm flagella 21S dynein. Tub., tubulin; 80K, an 80,000- M_r MAP.

Methods. Unfertilized sea urchin eggs were washed, dejellied and homogenized in 'extraction buffer' (0.1 M PIPES, 2.5 mM $Mg(CH_3COO)_2$, 5 mM EGTA, 0.1 mM EDTA, 0.9 M glycerol, 0.1 mM phenylmethylsulphonyl fluoride, $1 \mu g ml^{-1}$ pepstatin, $1 \mu g ml^{-1}$ leupeptin, $10 \mu g ml^{-1}$ aprotinin, 0.5 mM dithiothreitol, pH 6.9), then centrifuged to yield the cytoplasmic extract¹³ in which microtubules were assembled by incubation with taxol and GTP^{13,28} for 20 min. 0.1 M AMPPNP in extraction buffer was then added to a final concentration of 5 mM to one aliquot for a further 10 min, while a control aliquot was incubated with an equal volume of extraction buffer. One sample of extract was treated with 100 μM colchicine instead of taxol to inhibit microtubule assembly, then supplemented with 5 mM AMPPNP. These extracts were centrifuged through a 15% sucrose cushion¹³. The SDS gel system used here contained 6% acrylamide plus 0.06% bis-acrylamide. The low concentration of cross-linker allows easy visualization of the dynein heavy chain. Other biochemical procedures were performed as described previously¹³.

cytoplasmic microtubule-based motility (rather than serving as a precursor for embryonic cilia) is equivocal. Microtubule-associated ATPases have been prepared from other tissues (reviewed in ref. 12), but their role in cytoplasmic motility is also unknown. Recent work on axoplasmic transport, however, has led to the identification of a novel mechanochemical protein called kinesin²⁰, which is thought to generate the force for moving vesicles along axonal microtubules²⁰⁻²⁷. These results suggest that kinesin may also be a mechanochemical factor for non-axoplasmic forms of microtubule-based motility, such as mitosis. We describe here the identification and isolation of a kinesin-like protein from the cytoplasm of sea urchin eggs. We present evidence that this protein is localized in the mitotic spindle, and propose that it may be a mechanochemical factor for some form of motility associated with the mitotic spindle.

Extracts of squid axoplasm will support a microtubule-based, ATP-dependent movement of vesicles²⁰⁻²⁷. This motility is driven by a translocator that exists primarily in soluble form, with a fraction serving to cross-link microtubules to the moving vesicles²⁴. The non-hydrolysable ATP analogue, adenylyl imidodiphosphate (AMPPNP) 'freezes' vesicle motion on microtubules^{22,24,26}, suggesting that the analogue induces strong bind-

Fig. 2 Biogel A5M chromatography of sea urchin egg MAPs. Microtubules (MT, two different loadings) prepared in AMPPNP were washed in extraction buffer supplemented with 75 mM NaCl. The 134K polypeptide (134K) and putative dynein heavy chain (Dyn.) were extracted from the microtubules by differential centrifugation in buffer containing 0.1 M NaCl/10 mM $MgSO_4$ /7.5 mM ATP (lane A), then fractionated on a 1.2×20 -cm column of Biogel A5M. Fractions of 50 drops were collected, then 40- μl aliquots were analysed on SDS gels (lanes 7-18). Fraction 8 represents the void volume (V_0) and fraction 17 is the included volume (V_i). Aliquots (100 μl) of each fraction were frozen in liquid nitrogen, then transported on dry ice by Federal Express to the Marine Biological Laboratories, Woods Hole, where R. D. Vale and M. P. Sheetz analysed them for their ability to induce microtubules to move relative to other microtubules 'in vitro' as described by Vale *et al.*²⁰ for squid and bovine brain kinesin. The numbers beneath each column fraction represent the maximum dilution factor at which motility-inducing activity can still be detected. 0 = No motility observed. Vale and Sheetz did not know the polypeptide composition of the samples before assay. Note that motility-inducing activity co-elutes with the 134K polypeptide, the most active fraction being 13 ($K_{av} = 0.56$).

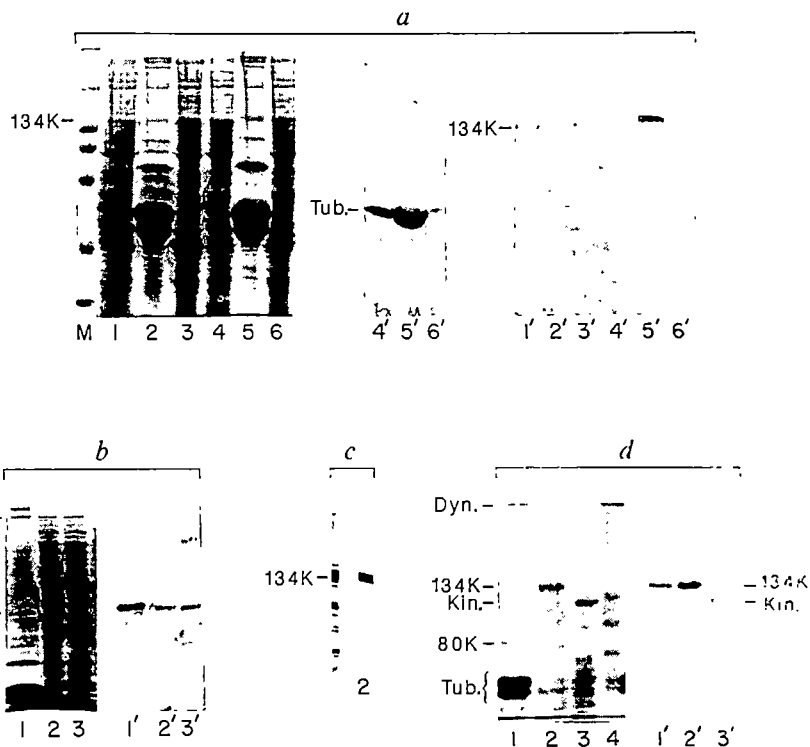

ing between the translocators and microtubules, thereby driving the translocators from a soluble to a bound form. We reasoned that AMPPNP might enhance microtubule binding of the translocators present in cytoplasmic extracts, so that microtubules prepared in AMPPNP might serve as an affinity matrix for identifying and isolating these mechanochemical proteins.

Taxol-assembled microtubules were therefore prepared from cytoplasmic extracts of unfertilized sea urchin eggs^{13,28} in the presence and absence of 1-5 mM AMPPNP. The amount of various microtubule-associated proteins (MAPs) co-sedimenting with tubulin was determined by densitometry of SDS-polyacrylamide gels (Fig. 1). We previously reported that a cytoplasmic dynein-like protein present in sea urchin egg extracts exists in both soluble and microtubule-associated forms^{13,14}. Only a small increase in the amount of the putative dynein heavy chain was observed in microtubules pelleted in the presence compared with the absence of AMPPNP (0.6 compared with 0.4 mol per 100 mol tubulin). Furthermore, we observed no significant increase in the ATPase activity which co-pelleted with the microtubules in the presence of AMPPNP (microtubules + AMPPNP: specific activity ~ 10 nmol per min per mg, total activity 31 nmol per min; microtubules - AMPPNP: specific activity ~ 13 nmol per min per mg, total activity 36 nmol per min). These results suggest that cytoplasmic dynein interacts with microtubules differently from the squid axoplasmic vesicle translocator^{22,24,26}; they do not support the hypothesis that cytoplasmic dynein is the motor for vesicle transport.

Addition of AMPPNP did, however, greatly enhance the amount of a polypeptide of relative molecular mass (M_r) 134,000 (134K) which co-sedimented with microtubules (Fig. 1) (~ 8 mol 134K per 100 mol tubulin compared with ~ 1 mol 134K per 100 mol tubulin without AMPPNP). Identical results were obtained when an egg extract was treated with 1 mM ADP plus 100 μM Na_3VO_4 , or when the ATP concentration in the extract was depleted by incubation with apyrase. The 134K polypeptide

Fig. 3 Antibody to the sea urchin egg 134K polypeptide stains a 134K polypeptide in immunoblots of cytoplasmic microtubules prepared in AMPPNP (*a*) and isolated mitotic spindles (*b*). It also reacts with the 110K polypeptide of squid kinesin (*d*). *a*, 7.5% SDS gels of microtubules prepared in the presence and absence of AMPPNP (Fig. 1). Lanes 1–6, Coomassie blue-stained gel; lane M shows M_r markers: 200,000; 116,000; 96,000; 68,000; 44,000; and 29,000. Lanes 1, 4, cytoplasmic extracts; lane 2, microtubules prepared in the absence of AMPPNP; lane 5, microtubules prepared in the presence of AMPPNP; lanes 3, 6, the corresponding supernatants. Immunoblots of corresponding lanes (1'–6') probed with anti-tubulin¹³ (Tub.) and 134K antibody are also shown. The 134K antibody reacts with a 134K polypeptide in microtubules pelleted in the presence (lane 5') but not in the absence (lane 2') of AMPPNP. *b*, The 6% polyacrylamide gels (lanes 1–3) and corresponding anti-134K immunoblots (lanes 1'–3') show microtubules prepared in the presence of AMPPNP (lanes 1, 1') and mitotic spindles which were isolated³² in the presence (lanes 2, 2') and absence (lanes 3, 3') of AMPPNP. An immunoreactive 134K polypeptide is present in spindles isolated either way. *c*, Blot-affinity purification^{29–31} of 134K antibodies. Lane 1, a nitrocellulose strip of 'AMPPNP' microtubules probed with whole 134K antiserum. Lane 2 was probed with affinity-purified antibodies eluted from 134K polypeptide/nitrocellulose strips²⁹. *d*, Cross-reaction of sea urchin egg 134K antibody with squid axoplasmic kinesin. The Coomassie blue-stained gel (lanes 1–4) and corresponding anti-134K immunoblot (lanes 1'–3') show microtubules prepared from fertilized sea urchin eggs in the presence of AMPPNP (lanes 1, 1'), sea urchin egg kinesin (lanes 2, 2') and purified squid axoplasmic kinesin (lanes 3, 3'). Lane 4, a 21S dynein marker. The 134K urchin polypeptide and the 110K squid kinesin polypeptide (Kin.) are indicated.

Methods. Two rabbits were injected at 2–3-week intervals with 134K polypeptide excised from stained-destained SDS gels of proteins extracted from 'AMPPNP-microtubules' in ATP + NaCl, over a period of 4 months. No 134K antibodies were detected in preimmune sera from either rabbit, but 134K antibodies could be detected on immunoblots at dilution 1:1,000 after the first and all subsequent booster injections.

did not pellet from AMPPNP-treated cytoplasmic extracts of unfertilized sea urchin eggs in which microtubule assembly was inhibited by treatment with colchicine (Fig. 1). Therefore, in the presence of AMPPNP, the recovery of this polypeptide in the microtubule pellet depends on its binding to the microtubules. The polypeptide composition of taxol-assembled microtubules prepared in the presence of AMPPNP was unchanged by the addition of 0.1% Triton X-100, suggesting that the 134K polypeptide is not associated with membranous vesicles. Similar results were obtained when cytoplasmic extracts of fertilized eggs were used to prepare microtubules.

Like the cytoplasmic dynein heavy chain, the 134K polypeptide was not released from the microtubules by differential centrifugation in the original egg extraction buffer containing 75 mM NaCl, but it was partially extracted using 5–10 mM Mg-ATP, and completely extracted using 0.5 M NaCl or 0.1 M NaCl, 7.5–10 mM ATP plus 10 mM MgSO₄ (Figs 1, 2). As the latter procedure gave the most efficient and specific extraction of 134K protein, this material was used for further purification by gel filtration chromatography (Fig. 2).

The sea urchin egg 134K protein resembles kinesin²⁰ in several respects. (1) The binding of both proteins to microtubules is greatly enhanced by AMPPNP; (2) they are extracted from microtubules in 0.1 M NaCl plus 10 mM Mg-ATP; (3) their elution behaviour on gel filtration columns suggests that they contain multiple subunits; (4) fractions containing the sea urchin egg 134K polypeptide cause microtubules to move relative to other microtubules, and beads to translocate along microtubules 'in vitro' in a manner very similar to squid kinesin (Fig. 2). These results strongly suggest that the 134K polypeptide represents sea urchin egg kinesin.

Specific antisera were raised against the sea urchin 134K polypeptide by injecting rabbits with electrophoretically purified 134K polypeptide. These antibodies stained the 134K polypep-

tide present in immunoblots of microtubules pelleted from egg extracts in the presence of AMPPNP (Fig. 3). This 134K antigen was enriched in microtubule pellets relative to the original cytoplasmic extracts, but it was not observed in immunoblots of pellets prepared in the absence of AMPPNP (Fig. 3). To analyse the immunological relatedness of the sea urchin 134K polypeptide and squid axoplasmic kinesin, blots of both proteins were probed with the anti-134K antiserum (Fig. 3d) or with blot-affinity-purified 134K antibody (Fig. 3c)^{29,31}. The 134K antibody exhibited a clear cross-reaction with the major polypeptide component (M_r ~110K) of purified squid axoplasmic kinesin. Furthermore, antibodies affinity-purified from the 134K antisera on blots of the squid kinesin 110K polypeptide also cross-reacted with the sea urchin 134K polypeptide (data not shown). These data strongly suggest that the sea urchin egg 134K polypeptide represents kinesin. It is interesting that the M_r s of squid axoplasmic kinesin (110,000; ref. 20) and sea urchin egg kinesin (~134,000) are clearly different (Fig. 3).

The observation that a kinesin-like protein is associated with microtubules from the cytoplasm of sea urchin eggs, where chromosome movement is a major function of these structures, suggested that kinesin might be a component of the mitotic spindle. Immunoblots of mitotic spindles isolated from sea urchin embryos³² showed that antibodies to the 134K protein recognized a polypeptide of appropriate M_r in spindles isolated with or without AMPPNP. It is uncertain why AMPPNP is not required for association of the 134K protein with spindle isolates. However, since the isolation protocol involves egg lysis in ~100 volumes of buffer containing no ATP, the resulting depletion of ATP concentration may be sufficient to enhance microtubule-binding by the 134K protein.

The localization of the 134K polypeptide in fixed mitotic sea urchin eggs was investigated by immunoperoxidase light microscopy using blot-affinity-purified 134K antibodies (Fig. 4)

Fig. 4 Immunoperoxidase light microscopic localization of the 134K kinesin-like protein in dividing sea urchin embryos. *a*, A low-magnification view of lysed cells stained with blot affinity-purified 134K antibody, showing clear spindle staining. Whole immune sera (diluted 1:100–1:1,000) from both rabbits also exhibited clear spindle staining, whereas corresponding preimmune sera exhibited no microtubule staining. *b*, Control lacking primary antibody. *c*, High-magnification view of a lysed cell stained with blot-affinity-purified 134K antibody, showing clear localization of the 134K polypeptide in the spindle fibres. *d*, Staining of an unlysed dividing blastomere. Note the concentration of the 134K protein in the mitotic spindle region. The approximate magnifications are: *a*, *b*, $\times 100$; *c*, $\times 700$; *d*, $\times 500$.

Methods. Sea urchin eggs were fertilized, allowed to progress to metaphase and fixed in 90% methanol plus 50 mM EGTA with or without prior lysis in 0.5% Nonidet P-40 (ref. 37). The fixed cells were incubated with blot-affinity-purified 134K antibodies and processed for peroxidase-antiperoxidase (PAP) staining and bright-field light microscopy.

The antibodies were checked for monospecificity on immunoblots of whole egg homogenates before use. Spindle staining was obvious (Fig. 4*a*). Observations of unlysed metaphase eggs stained with the affinity-purified 134K antibody revealed that the corresponding antigen is present throughout the cytoplasm, but is highly concentrated in the mitotic spindle (Fig. 4*d*). This pattern may reflect the existence of pools of soluble kinesin (accounting for background staining) and microtubule-associated kinesin (producing the spindle staining). Tubulin is believed to exhibit a similar distribution in dividing sea urchin eggs³³. When the blastomeres were lysed with detergent before fixation, clear staining of both chromosome-to-pole and astral fibres was evident (Fig. 4*c*). Several control experiments confirmed that staining was specific for 134K antibodies. (1) No microtubule staining was observed with preimmune sera or when the cells were incubated with secondary antibodies alone (Fig. 4*b*). (2) When 134K antibodies were preincubated with the 134K protein prepared by gel filtration chromatography (Fig. 2), no microtubule staining was observed by subsequent immunoperoxidase light microscopy. (3) Preabsorption of the 134K antibody with bovine brain tubulin did not affect staining. (4) Antibodies prepared from the 134K antisera by blot-affinity purification against the squid kinesin 110K polypeptide also stained the spindle fibres by immunoperoxidase light microscopy. These results strongly suggest that spindle staining is not due to a contaminating 134K polypeptide in our sea urchin microtubule preparations, but rather to the presence of a kinesin-like protein in the spindle fibres.

We propose that the 134K polypeptide represents a cytoplasmic form of kinesin which is associated with the mitotic spindle in dividing sea urchin embryos. The observations that kinesin induces microtubule-based motility *in vitro* suggest that it may also promote motility within the cell, so it is tempting to speculate that the sea urchin protein performs a mechanochemical function within the mitotic spindle. For example, it may cause microtubules to slide relative to other microtubules or to some other components of the spindle, or it may cause chromosomes to be translocated along microtubules. Alternatively, cytoplasmic kinesin may not be directly involved in chromosome movement, but may instead be involved in moving 'particles or states' along microtubules in the metaphase half-spindle (see, for example, ref. 34). To distinguish between such possibilities and to elucidate the function of kinesin within the cell, other techniques such as antibody microinjection into living cells³⁵ are being used.

A predicted property of kinesin is ATPase activity. Interestingly, since this manuscript was submitted, Brady reported³⁶ that the AMPPNP-dependent binding of a 130K polypeptide to chick brain microtubules accompanies an increase in the ATPase activity of the microtubules. However, the exact relationship between this ATPase and kinesin is not yet established.

We thank Drs Ron Vale and Mike Sheetz of the NIH NINCDS group at the Marine Biological Laboratories, Woods Hole, for providing squid axoplasmic kinesin and for performing motility assays on the sea urchin egg protein. Their results and the characterization of the sea urchin protein will be described elsewhere. We also thank numerous colleagues for their interest in this work, Larry Harwood for photography and Cathy Inouye and Karen Brown for secretarial assistance. J.M.S. particularly thanks Bonnie Neighbors for advice on immunoperoxidase light microscopy. Taxol was a gift of Dr M. Suffness (National Products Branch, NCI). J.M.S. was supported by an MRC Travelling Fellowship and a British-American exchange fellowship from the British Heart Foundation and American Heart Association. M.E.P. was supported by a fellowship from the Helen Hay Whitney Foundation. This work was supported by NIH grant GM 30213 and American Cancer Society grant BC-498 to J.R.M.

A molecular solution to the riddle of the giant panda's phylogeny

O'BRIEN *et al.*¹ predict "the existence of older Pliocene or even Miocene fossils of the ancestors of the giant panda". In fact, a putative ancestor was identified by Thenius² in 1979. This is *Agriarctos Kretzoi*, described on mandibular dental material from the late Miocene of Hungary. This ursid shows incipient molarization of the premolars apparently foreshadowing the condition in *Ailuropoda*.

This is independent support of the conclusions reached by O'Brien *et al.*, including their suggestion that *Ailuropoda* (with *Agriarctos*) may be assigned to a subfamily (*Ailuropodinae*) of the family Ursidae.

Steens Mountain geomagnetic polarity transition is a single phenomenon

IN their reinterpretation of the transition recorded in the Steens Mountain lavas¹, Valet *et al.*² suggest that the second phase (the 'rebound') occurred at a significantly later time than the first phase (the reverse-to-normal transition). In this way they attempt to separate what is one phenomenon into two separate phenomena, and assert that the second phase is a geomagnetic excursion unrelated to the preceding reversal. Several lines of evidence indicate that there was no significant hiatus in eruptive activity in the part of the lava section on Steens Mountain sampled by us and previously by Watkins³.

First, there are no soil horizons, weathered zones or interbasaltic sedimentary rocks or sediments anywhere in the sampled section, except some negligible baked earths (tuffs, perhaps) that we found in two restricted localities stratigraphically unrelated to the limits of either of the two transition phases. Moreover, the lavas are of rather uniform composition, and the only obvious lithological variability between successive lavas is the presence or absence of large platy labradorite phenocrysts up to 4 cm in diameter. The occurrence of these porphyritic lavas is unrelated to any aspect of the polarity transition.

Second, Gunn and Watkins^{4,5} made many complete chemical analyses of the

Table 1 Chemical groups⁵ and directional groups¹ for Steens lava analyses

Chemical group	Directional group
A, B	1-10
C	10-12
D	12-20
E	21-26
F	26-28
G	30-42
H	42-55

Table 2 Recalculated K-Ar ages

Watkins flow no. ^{1,5}	Directional group ¹	Age (Myr)
11	~4	15.5 ± 0.15
17	~10	15.4 ± 0.13
51	33	15.5 ± 0.28
61	43	15.4 ± 0.25
68	49	15.6 ± 0.21
70	49	15.3 ± 0.21

The uncertainty is 1 s.d. of the data.

Steens lavas. Table 1 shows how their chemical groups correspond to our directional groups. The first phase of the reversal begins with directional groups 43 and ends with group 30, and the second phase begins with group 28 and ends with group 15. The variations in chemical composition are uncorrelated with any aspect of the palaeomagnetic record, and several of the chemical boundaries occur within directional groups. The only possible peculiarity is that Gunn and Watkins analysed a high-alumina flow and a pyroxene-rich flow in chemical group F, which corresponds to the beginning of the second phase. These lavas, however, are perfectly correlated with the others, as demonstrated by an alumina variation diagram⁵.

Third, there is no discernible age difference between the top and bottom of the sampled section. We have recalculated

and averaged the K-Ar ages published by Baksi *et al.*⁶ and they are given in Table 2 (new decay constants).

Thus, the available field observations and geochemical and geochronological data directly contradict the suggestion of Valet *et al.*² that the two phases described in our article¹ may not belong to a single geomagnetic process.

VALET, LAJ AND TUCHOLKA REPLY—

In some of the reversal records that we have obtained from sedimentary sections in Greece (work partly published and presented at IAGA Praga 1985), we have also observed excursions occurring either before or after the transition. In all these cases the characteristics of the directional changes during both the polarity transition and the excursions are similar. The continuity of the sedimentary records also shows that the duration of the excursions never exceeds the time span of the transition.

In the Steens Mountain record¹, the first phase is quite similar to a sedimentary reversal record but, in striking contrast to our observations, the second phase is dissimilar. Furthermore, between the two phases the geomagnetic field has recovered high intensity and dipolar direction. The authors consider the two phases as a single phenomenon. In an attempt to reconcile sedimentary and volcanic records, we have suggested² that the widely different symmetry properties could indicate two unrelated different phenomena.

The existence of rebounds or oscillations associated with a reversal is an important problem which, as Prévot *et al.* suggest¹, may be crucial to our understanding of geomagnetic reversals. Clearly, what is needed is a criterion to establish when an excursion is connected to a reversal. The argument of continuity

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

suggested by Prévot *et al.* can reasonably be used as such a criterion. However, if the continuity can usually be well established in sedimentary records, this appears to us much more difficult in volcanic records. Furthermore, despite the additional information given here by Grommé *et al.*, we are not fully convinced that any of their arguments provide compelling evidence of a continuous mean extrusion rate on a timescale of less than 1,000 yr.

The rather uniform composition of lavas can hardly be used in this sense, as periods of constant chemical composition lasting up to about 150,000 yr have been observed, for example, in Etna³. We agree that the K-Ar dating results really indicate the same age for the top and bottom parts of the sequence. However, differences of about 0.3 Myr inside the same directional group (No. 49) are observed and if standard deviation is taken into account, the time span of age could reach 0.7 Myr.

Finally, the argument of the secular variation used by Prévot *et al.*¹ to establish the linearity of timescale is also not convincing. Neither the number attached to the angular displacement of directions nor the stability of the secular variation over long periods of time is confirmed in longer records of secular variation, in lake sediments⁴ or by comparison of lake sediments and recent lavas⁵.

We are convinced that the data obtained by Prévot *et al.* provide a very impressive description of the geomagnetic field during a transition. What we are saying is that, in the present state of knowledge (or ignorance), part of the interpretation of this record might still be open to discussion.

Dust production in the Sahel

I WISH to make three points concerning the adequacy and consistency of the Sudanese visibility data used by Middleton in a recent analysis¹ relating the frequency of severe atmospheric dust occurrences to annual rainfall.

First, after 1974, the Sudan Meteorological Service started recording visibility

at 00.00 GMT in addition to 06.00, 12.00 and 18.00. Frequencies of poor visibility presented by Middleton for El Fasher in Fig. 1 (and for five Sudanese stations in Table 2) are therefore inflated for the years 1975-78 compared with previous years. Second, each observation of poor visibility does not necessarily refer to a separate dust storm event. Poor visibility at 06.00, 12.00 and 18.00 may be the continuation of a single storm whereas Middleton would categorize these as three separate storms. The resolution of the Sudanese data is insufficient to make this distinction. Again, the caption for El Fasher in Fig. 1 is misleading and the data are almost certainly inflated.

Finally, and most important, no discussion of the reliability of the visibility readings is included. Atmospheric visibility is a notoriously difficult climatic parameter to quantify. The Sudan Meteorological Service used the system of locating key landmarks at known distances from the observing station which are recorded either as seen or unseen by the observer at the designated times. I have observed ephemeral objects such as trees and electric lights being used at Sudanese stations. I would treat with great caution data collected in such a manner, where differences in procedure between successive observers can be crucial.

An inverse relationship between the recorded frequency of dust events and annual rainfall does appear to exist (subject to my first and second points) and the analysis is useful. I suggest, however, that climatic data from Sahelian countries be treated cautiously and their measurement and collection procedures carefully investigated and understood before they are analysed.

M. HULME

Department of Geography,
University of Salford,
Salford M5 4WT, UK

1. Middleton, N. J. *Nature* **316**, 431-434 (1985).

MIDDLETON REPLIES—I thank Dr Hulme for his interest. Dust storms are recorded by meteorological observers using fixed objects as visibility targets in all countries of the world where such phenomena occur, and such observations do present problems of observer error and involve an element of subjective decision making. As with all meteorological data there may also be changes in observational procedures. There are other problems inherent in interpreting data on the frequency of dust storms and dust storm days; I have highlighted some of the problems in a recent paper¹. Briefly, the statistics may conceal considerable variation in the areal and volumetric extent of dust storms and their duration. However, some of these problems are less serious when a

group of stations is used² to illustrate a particular trend in dust storm activity.

There may well be some inflation in the data for the Sudanese stations since 1974 as a result of a change in the frequency of visibility recording to which Hulme correctly refers, but the increasing trend that started before 1974 has continued to rise since that date and seems to be confirmed by studies in other countries of the Sudano-Sahelian belt. Note also that mean summer concentrations of dust at Barbados were again very high during 1982 and 1983 (ref. 3), although any comparison of dust storm frequency with dust mobilization or transport should be cautious because the scale of dust-raising events and the altitude to which material is lifted are of fundamental importance to the long-range transport of dust, and such information is not provided by dust storm frequency data for a particular station, as mentioned above.

New looks at spectroscopy

More spectroscopic equipment is becoming interfaceable with desktop computers — and even the Bunsen burner is going high-tech.

- Weighing only 2 pounds and compact in size, the Spectra-Physics IR minimonochromator system (Model SP5155) covers the 2.7–30 μm region. The optical configuration is that of an Ebert monochromator with grating blaze options. Standard interface optics packages are available for interfacing the unit with Spectra-Physics tunable diode lasers and the SP5800 laser source assembly. The minimonochromator is a product of the Laser Analytics Division of Spectra-Physics.

Reader Service No. 100.

IR minimonochromator system SP5155.

- The new RC, high efficiency recirculating coolers from New Brunswick provide a continuous and reliable capacity from 750 to 58,500 watts and allow fluid temperature control between -40°C to $+75^{\circ}\text{C}$ with accuracy of 0.5°C . Coupled with one of the variety of built-in pumps available these recirculating coolers are ideal for the heat removal requirements of most laser systems. The optional digital controller and IEEE/488 bus allow computer control of the system for complete automation.

Reader Service No. 101.

- The Varian VXR series NMR spectrometers are superconducting Fourier transform instruments functioning at 100, 200, 300, 400 and 500 MHz. All critical spectrometer functions are under computer control, and components are modular for high reliability, ease of maintenance and for easy upgrading. For data manipulation and experiment management, the multiple processor-based VXR 4000 data station includes a 68000-based computer and a Winchester capacity of up to 160 Megabytes. The VXR 4000 may use optional networking capabilities including Ethernet, Varian's magNET and Serial Communications software. For data processing and display, the VXR 4000 may be purchased as an independent work station.

Reader Service No. 102.

These notes are based on information provided by the manufacturers. To obtain further details about these products use the reader service card bound inside the journal.

- A self-contained extract system for atomic absorption spectrophotometers is now available in kit form from Mason Nordia. The extract system will protect the operator against toxic fumes and protects the instrument against corrosive vapours. To reduce the risk of heat gain in the laboratory, the kit has specific capability to overcome problems of heat concentration where the flame generates 3kW or more of heat.

Reader Service No. 103.

- The latest catalogue on optical table and isolation systems from Photon Control of Cambridge includes: large high performance metal honeycomb and synthetic granite optical tables designed to meet the needs of the laser and optical scientist; up-to-date modular designed vibration isolation systems; and special purpose tables and vibration isolation systems on which to mount precision instruments and sensitive equipment. Use the readers service to obtain a free catalogue.

- Blak-Ray UV intensity meters are designed for monitoring the efficiency and uniformity of UV light sources. The J-225 model measures in the short-wave range from 220 to 280 nm with peak sensitivity at 254 nm. Long-wave readings are made with the J-221 model with a range from 300 to 400 nm and a peak sensitivity at 365 nm. Readings are given in $\mu\text{W cm}^{-2}$. Sensors plug directly into the top of the meter housing. Readings in hard-to-reach locations are made using a 4-foot cable to connect the sensor to the meter. Each model features a A and B Scale for low or high intensity readings. A selector switch chooses the scale, and a snap-on accessory filter provides true UV readings with infrared present.

Reader Service No. 105.

- A new infrared detector is available for the Rofin-Sinar optical spectrum analysis system. The detector enables the system to rapidly scan optical spectra in the 1.5 to 4.5 μm wavelength region with a resolution of 20nm. The resulting spectral data (10 scans per second) may be displayed in real time on a standard laboratory oscilloscope or it may be processed by an Apple or BBC computer before being displayed on a monitor or printer. The detector unit, model RSO 6115, uses a PbSe element as the optical transducer and it is supplied with a stabilizer bias power supply, a signal pre-amplifier, and all the necessary mounting hardware for easy connection to the RSO 6140 scanning monochromator.

LKB's PC-interfaceable liquid chromatography.

- LKB-Produkter AB of Sweden has developed extended PC software for its diode array detector for use in liquid chromatography. This new Wavescan software makes it possible to automate diode array detection even further, and offers a significant increase in post-run analytical productivity. Designed for the PC, XT, AT or any IBM compatible, Wavescan programs use a simple menu technique. With instant access to isograms, chromatograms and spectra, it is possible to obtain considerably more detailed information on sample identity and purity.

High-tech 'Bunsen'

THE conventional Bunsen burner may be a thing of the past. From Technomara of France comes the Fireboy, with an electronically controlled gas flame. Exotic features include a provision for a control pedal operated by the foot to free both hands for experimental procedures, and accurate control of the flame temperature. Reader Service No. 108.

• Questek excimer lasers, available from Lambda Photometrics, provide high power UV pulses (40–750MJ) at any one of a number of fixed wavelengths. A new 20-page brochure is now available, giving full technical details, applications data and suggestions on selecting the right model. *Reader Service No. 109.*

• Australian Monoclonal Development (AMD) now offers a T-cell panel for enumeration of total T cells and T-cell subsets using the indirect immunofluorescence method. The AMD T-cell panel includes three monoclonal antibodies: T4, T8 and T11 equivalents, plus FITC anti-mouse Ig conjugate. Future releases will include a conjugated panel of the same antibodies. These reagents are currently being used routinely to determine T4/T8 ratios in suspected AIDS patients and also to observe T cell imbalances in other immunological diseases. AMD will soon be marketing two other tests for clinical use. The Monohaem kit is a reliable immunoassay for occult blood in faeces and is based on a monoclonal antibody which is specific for human haemoglobin. The AMD Gono-kit uses a panel of monoclonal antibodies which covers all strains of *N. gonorrhoeae* for definitive identification by direct immunofluorescence on clinical specimens. *Reader Service No. 110.*

• New from SLT Labinstruments, the SLT Easy Reader plate photometer is designed with enzyme-linked immunosorbent assay in mind. The Easy-Reader is ideal for low volumes, combining fast, accurate measurements with sophisticated software for data evaluation. The Easy

SLT's Easy Reader.

Reader Measures the whole plate with one filter in 20 seconds and for dual wavelength measurements it takes only 35 seconds. *Reader Service No. 111.*

• Hewlett-Packard's HP 9000 computer with enhanced mass-spectrometer software will enhance the performance of the HP 5970B mass-selective detector (MSD), HP 5995C GC/MS, and HP 5988A GC/MS and LC/MS systems. The workstation combines enhanced GC/MS, LC/MS and MSD software with the new HP 9000 Series 300 technical desktop computer, which is designed specifically for instrument control and scientific-data handling. *Reader Service No. 112.*

The largest solar panels on the market, from Solarex. The modules are available as 145, 290 and 435 watt units and achieve a high efficiency of 12.4%. *Reader Service No. 113.*

• Now available in the UK from Baird & Tatlock, the Cecil range of UV/visible spectrophotometers provides three single-beam models, each with a choice of four systems. The three models available have a wavelength range of 190 to 990nm and a wavelength accuracy within 1nm. The models are: CE2202, measuring transmittance and absorbance on a meter scale, ideal for teaching or routine work; CE2272, with a linear scale for transmittance, concentration and wide scale expansion ranges for absorbance; and CE2293, with a digital scale for absorbance transmittance and concentration. It also has the option of computer interfacing, data handling and an autozero facility. *Reader Service No. 114.*

• Rigaku manufactures two similar X-ray fluorescent spectrometers — the 3070 and the 3071. The 3070 spectrometer has normal optics; the 3071 features inverse optics. The 3071 allows for greater ease of liquid sample handling and analysis, whilst retaining the same features as the 3070 model. Both are menu-driven for ease of operation, with an internal-external sample chamber for continuous feed analysis, spectrometer status display, full data reduction capabilities, spectrum marker elemental identification and computer controlled pulse height analyser. *Reader Service No. 115.*

• New options on the Perkin-Elmer 1700 Series of Fourier transform infrared spectrometers include an extended near IR range. The standard model 1750 now scans to 5,000 cm^{-1} in the near infrared, a region of the spectrum particularly useful for quantitative analysis in the polymer industry. Model 1710 scans to 4,400 cm^{-1} , and this wavelength range is extended to 5,000 cm^{-1} when the spectrometer is used with the model 3600 data station. And a caesium iodide beamsplitter is now available as an alternative to the standard KBr beamsplitter. Fitted with this, the model 1710 scans from 4,300 cm^{-1} to 220 cm^{-1} and model 1750 from 5,000 cm^{-1} to 220 cm^{-1} . *Reader Service No. 116.*

• VG Isotopes, specialists in isotopic and elemental mass spectrometry, has announced a new analytical research service for scientists, researchers and technologists. VG Isotopes Analytical Service Group has at its disposal an array of techniques including inductively coupled plasma mass spectrometry (ICP-MS), glow discharge mass spectrometry (GDMS) and thermal ionization mass spectrometry (TIMS). The analytical service should be particularly attractive to those who would not otherwise have access to such advanced instrumentation, or need only occasional access to such equipment. *Reader Service No. 117.*

• The Gilford Response range of UV/Vis spectrophotometers from Ciba Corning has now been extended to three separate models. Common to all models is: an autoranging photometer; transverse sample compartment; high resolution graphics; data storage facilities and a 16-bit resident computer. The basic Response is supplied complete with a single cell holder and programs for: wavelength scanning; kinetics; time scanning; multi-wavelength analysis; standard curves and sample read. The second unit has an automatic six-position cell holder as standard and has the capability of adding gel scanning, rapid sampling and a six-position thermostet cuvette holder for electronic control of sample temperature. The most advanced Response has two disk drives for archival data storage, together with extended software applications. *Reader Service No. 118.*

• Cuvette sample packs are being offered by Elkay Products Inc. free of charge to laboratories wishing to evaluate the company's six different disposable cuvettes. Precision moulded in UV-inhibitorless polystyrene or acrylic copolymer, the cuvettes are capable of averaging 70% light transmittance at 340 nm. Each cuvette is packed in particle free, shrink wrapped reusable polyfoam trays.

Reader Service No. 122.

Free cuvettes from Elkay.

• Beckman's data capture software for use with DU-7 and DU-50 UV/Vis spectrophotometers is compatible with the IBM PC series of desk-top computers and features colour graphics with easy colour selection. The software allows single-wavelength, scanning, kinetics and gel scan data to be transferred to the computer and conveniently stored in labelled files on standard disks. With the DU-7 spectrophotometer stored data can be transferred bidirectionally so that data from disk may be viewed and manipulated on the graphical video display of the DU-7. With the DU-50 series stored data can be displayed quickly on the computer's monitor with overlay of curves in different colours, and scans can be added and subtracted to give accumulated results or difference spectra. All data are stored in a standard file format which is directly compatible with such popular general software as Lotus 1-2-3. With Lotus, data can be entered into a spreadsheet presentation for carrying out complex calculations and data manipulation.

• For those involved in the study of rapid reaction intermediates, Hi-Tech has introduced the SFL-43 stopped-flow/multimixing flow module as an additional capability to the SF-4 spectrophotometer system. This flow module can be used in two modes in the study of reaction intermediates or just simply for high performance stopped-flow work. In the sequential mixing mode, two stable solutions are mixed to form a short-lived intermediate which in turn is mixed with a third reagent after a pre-set delay as short as 5 ms. The second reaction is studied by stopped-flow spectrophotometry. The preparative quench flow made enables a fast chemical or biochemical reaction, that

SFL-43 augments the SF-4.

lacks a suitable chromophore, to be analysed by an intrinsically slow technique such as NMR spectroscopy. Initiated by mixing, the reaction is stopped after a pre-set delay by mixing with a quench solution and the product is then collected for analysis. By varying the delay a series of values may be plotted to determine the reaction rate. The flow circuit is automatically purged by solvent before the run, thus eliminating cross-contamination.

IR frequencies analysed by Savant.

• An audiovisual training program on the interpretation of infrared spectra, written by J.H. van der Maas and E.T.G. Lutz has been published by Savant Audiovisuals and John Wiley. Composed of eight lessons which systematically cover the major IR group frequencies, the package contains 123 slides, four tapes, 10 course books, an answer book and 100 correlation tables. It is illustrated with high quality spectra of known compounds and unknown materials for student practice. This educational package (IR 1000) complements Savant's other infrared audiovisual programs which are concerned with techniques, instrumentation and applications. They cover infrared quantitative analysis (IR-101), solid sample handling for infrared spectroscopy (IR-102), infrared internal reflectance spectroscopy (IR-103) and computerized infrared spectroscopy (IR-104).

Reader Service No. 128.

• Burleigh Instruments, Inc. has introduced two new mirror sets which extend the spectral range of the company's SA-800 and SA-200 Series optical spectrum analysers. The new mirror sets cover the important wavelength regions of 800-900nm and 1.06 μ m. Burleigh spectrum analyser systems are modular and feature an x, y, theta and phi adjustable mount for complete control over the alignment process. Each system is delivered with spectrum analyser, controller, detector, beamsplitter, mount and bases. The analysers are being used extensively as a diagnostic for mode-locked YAG systems.

Reader Service No. 129.

Burleigh's RC-46 controller with accessories.

WPA S105 spectrophotometer.

• The S105 and S107 spectrophotometers from Walden Precision Apparatus are designed to cover the UV and IR ranges, operating between 380 and 920 nm. A slow motion wavelength selector control with a large scale and pointer is incorporated in these instruments. The scale is marked at 5-nm intervals and the approximate colours of the visible spectrum are shown to ensure accurate wavelength selection. The symmetrical optical system achieves a bandwidth of less than 5-nm and the illumination is provided by a special tungsten filament lamp which gives a continuum of emission from about 300 nm to well into the infrared spectrum. Both spectrophotometers accept standard glass or plastic 10 mm cuvettes which are shielded from extraneous light. A quick

The Bentham spectral analysis system with software.

- Bentham's new modular spectral analysis system can be used over the wavelength range from 200nm to 30 μ m. The system can as easily be configured for accurate colour measurement of displays as it can be for measurement of transmission and emission in the ultraviolet and infrared regions. Light sources, detectors and electronics including lock-in amplifiers are available, while system control is facilitated by the use of the IEEE/488 interface bus (GP-IB, HP-IB). Popular applications include colour measurement, for which calibrated standards are supplied, measurement of spectral loss in fibre optics and monitoring of plasma etching processes. A software package available for HP-85 and some other popular desk-tops perform general spectral measurement and fibre loss.

Reader Service No. 130.

- Polyspec, is a new microspectrophotometer from Reichert-Jung. It is a modular system comprising a basic system for measuring transmittance (extinction), reflectance or fluorescence which can be upgraded to microspectral analysis or to an integrated complete microscope measurement system with automatic scanning control. Providing high sensitivity and reproducibility, this new system permits observation of the measuring diaphragm during measurement by employing the synchronized dual chopper principle. The Polyspec has a choice of two operating modes — either the HP (high precision) chopped mode taking 140 measurements per second, or the HS (high speed) d.c.-mode at 1,000 measurements per second. The control unit employs 2 Z-80A microprocessors, it can be fitted with up to eight plug-in dedicated applications program modules, and has a liquid crystal display capable of graphics presentation. The Microspectrophotometer may be interfaced to a computer for programming and data processing and to a printer-plotter.

Reader Service No. 131.

Reichert-Jung's Polyspec.

- Philips Analytical has developed two new low-cost ultraviolet/visible spectrophotometer data systems based on the PU8800 series of instruments. The PU8800 DS system, designed for scanning work, consists of the high performance double beam PU8800 spectrophotometer, a computer customized for the laboratory environment, and a scanning software pack. The software permits spectral display, overlay and expansion using a zoom facility. Spectra, each containing up to 7,000 data points, can be stored on disk, together with optimized display parameters and PU8800 scan conditions. The second system, PU8800 DSK, is specially designed for kinetics and comprises a PU8800 spectrophotometer, computer, six-cell changer and an advanced kinetics software pack. Features include absorbance against time plots and rate calculation with linearity check. Printouts of rate, activity and purity can also be obtained. K_m and V_{max} values can be calculated by either a direct linear plot or regression analysis, and the plots and results displayed in a few seconds.

Reader Service No. 132.

The PU8800 UV/Vis spectrophotometer.

- A completely new analytical transmission electron microscope from Carl Zeiss (Oberkochen) incorporates a fully integrated electron loss spectrometer. This gives the Zeiss EM902 the capability of performing Electron Spectroscopic Imaging (ESI), providing significant improvements in contrast, and high resolution elemental mapping over conventional techniques. Using ESI it is possible to analyse and image light elements not accessible to X-ray microanalysis with sensitivities and resolutions not even theoretically attainable by X-ray spectrometry.

Reader Service No. 133.

- The latest issue of Finnigan MAT publication Spectra covers clinical applications of mass spectrometry and includes articles on organic acidurias in children, use of GC/MS in clinical toxicology, eicosanoid mass spectrometry and steroid profiling by GC/MS.

Reader Service No. 134.

- The Kratos Analytical MS80 is a high performance medium resolution mass spectrometer designed for both routine operation and advanced research problems. It features double focusing forward geometry that incorporates hexapoles, with advanced source construction and a novel magnet design that gives outstanding sensitivity maintained across the range of resolving power. Exceptional capabilities are available in quantitative selective ion monitoring, at picogram levels and below, of materials in complex mixtures. A comprehensive range of inlet systems includes gas chromatography, with facilities for packed and capillary column work. Fully programmed digital logic and display units give push-button control of major instrument functions. The fast scanning RF magnet is of particular use in capillary column GC/MS, both in terms of its fast scan speed and also in its speed of switching in magnetic selectors ion monitoring mode. The MS80 can be provided with an LC/MS inlet utilizing the Thermo-spray mode of operation.

Reader Service No. 135.

- A new mass spectrometer for automatic ^{15}N analysis has been introduced by VG Isogas, the ANA-SIRA (for Automatic Nitrogen Analyser-Stable Isotope Ratio Analyser) mass spectrometer system. The ANA-SIRA can automatically analyse both solid and liquid samples for ^{15}N and total N with sample sizes as low as 5 μg N at natural abundance. This combination of sample preparation and analysis enables fast (5 min per sample), reproducible (± 0.0005 atom % ^{15}N), and automatic analysis in the fields of biomedical, agricultural and environmental research. An ANA Interface upgrade kit is available for all VG Isogas mass spectrometers.

Graduate mobility in the United Kingdom

from Richard Pearson

Increasing interest is being paid in the United Kingdom to longer-term graduate careers; several cohort studies following graduates from 1980 and later years are now under way or are being planned.

Job prospects and employment patterns of new qualifying graduates are seen by many as an important indicator of higher education's "success" and relevance to industry. Others argue that they say nothing about lifetime returns from higher education which should not be exclusively job-related. Nevertheless, by providing an easily quantifiable indicator, trends and comparisons based on the first destination statistics will be made. While they provide a valuable barometer of initial labour market success, they are not a definitive statement of longer-term employment prospects. A typical working life lasts forty years or more and in the United Kingdom there are more than six million job changes each year. Evidence about employment status six months after graduation can provide only a starting point for assessing graduate careers.

In providing a broader context, a recently published study¹ of graduate mobility based on the experiences of 280 em-

ployees, original employer five years later. This may be in part explained by the low recruitment levels in this sector in the early 1980s resulting in a shortage of experienced graduates three to five years later which in turn encouraged mobility between employers. By contrast, only 26 per cent of those recruited by chemical companies in 1980 had left their initial employer in the following five years. More general evidence suggests that the retention curve flattens after five years or so, and that after 10 or 15 years probably 30 per cent of graduates are still with the same employer.

These studies show only general trends. The best source of data on the mobility of individual graduates remains the now dated study by the Department of Employment of 12,000 students and their careers and mobility over the seven years to 1977. That study showed that men graduates were more mobile than women graduates, both between their occupations and type of work, but that women were more likely to move between employment sectors. The main motivation of graduates in changing jobs was the "job interest" and "level of responsibility offered" but the prospects of a good salary and promotion assumed increased importance as their careers developed. Women's salaries were about 20 per cent below those of men after seven years, a difference only partly explained by the higher incidence of part-time work among women. The highest salaries were, in 1977, paid to graduates in social studies or engineering, the lowest to arts graduates. Managerial jobs in industry and commerce tended to be the best paid, while school teachers were among the lowest paid. It was also found to be less rewarding financially seven years after graduation to have studied and gained a postgraduate qualification than to have entered employment directly and gained work experience. This study is due to be repeated next year, based on the cohort graduating in 1980.

The most recent major survey of graduates' early careers has been that being undertaken by the Council for National Academic Awards (CNAA) which is surveying 10 per cent (2,600) of graduates who received CNAA degrees in 1982. The students were surveyed in 1983, 1984 and 1985, allowing a three-year profile to be drawn up of their early careers. The results of the 1983 survey reveal a complex pattern of transition over the first year into the labour market. They show significant numbers entering, for

example, part-time or temporary employment and one in six changing their job within the first year. In many of the "vocational" subjects such as pharmacy, nursing and business studies, the graduates were in their preferred job, but 40 per cent of all graduates and 60 per cent of scientists were looking for "something better". Nearly half the scientists felt over-qualified for the job they were then doing and one in six scientists had already had two or more jobs in their first year after graduation. A further 41 per cent had considered changing jobs. Nearly a year after graduation, the average salary for a scientist in 1983 was £4,867, considerably below that of engineers (£6,358) and maths/computer scientists (£6,354) but similar to

Fig. 1 Graduate retention. Taken from ref. 2.

that for social scientists (£4,865) and just ahead of the arts and humanities graduates (£4,672). The average salary across all subjects was £5,058. More than one in four of the CNAA scientists was unemployed ten months after graduation which is rather more than at the six months stage.

For graduates, like all other first time entrants into the labour market, the first job is only the first part of a career, the early years of which are likely to see several changes of job and possibly of employer. The first year for many can be a particularly difficult year of transition, especially, as in 1982, in times of a depressed labour market. The first destination statistics provide one snapshot, and give a limited performance measure; they do not however provide a complete picture of life after higher education.

Graduate retention 1974-79 and 1980-84

Retention dates	Year of cohorts*				
	5th	4th	3rd	2nd	1st
1974-79 cohort	54	59	71	84	96
1980-84 cohort	58	66	72	84	94

* 1st = most recent, that is 1979 and 1984 respectively.

ploying organizations showed that nearly 40 per cent of graduates recruited in 1980 were no longer with the same employer five years later. As Fig. 1 shows, there is a fairly standard decay curve, with 34 per cent of the 1981 cohort and 16 per cent of the 1983 cohort having left their initial employer by 1985. In addition, most graduates who have stayed with a single employer will also have changed jobs over this period and some will also have moved geographically. What is particularly interesting about the 1985 study is the comparison that can be made with the results of a similar study in 1980. The time span for each was five years, and each covered a similar economic cycle from a low to a high point of economic activity. Despite the fact that the recession of the 1980s and the contraction in job opportunities was far more severe, retention rates followed remarkably similar patterns (Fig. 1). Despite this consistency over time, there were differences between employers from different sectors. The sector with the highest loss was engineering, where 60 per cent of the 1980 graduates were no longer with their

Answering the \$144 billion question

The US Congress will probably have settled the course of the world's economy for a decade in the past few days of hectic pre-Christmas legislation. It may not have the leisure in which to repent.

ONE thing about the future is now certain. The US federal government's deficit for the financial year beginning in October 1986, whimsically called "Fiscal 1987", will be not a penny more than \$144,000 million, just about two-thirds of the likely deficit in the current financial year. And how can anybody be sure of that in such an uncertain field? Because the Congress will this week have passed a law to that effect and because President Reagan will not have dared to veto the bill for fear that the federal government will otherwise be unable to borrow the funds it needs to pay its bills, pre-Christmas salary cheques due to federal employees among them. More than this, the Congress has also decreed a linear decline of the annual deficit until, in fiscal 1991, it vanishes altogether. It is as if a government had decreed that the incidence of murder, or of AIDS, will decrease in four equal instalments to vanishing point.

Naturally, neither the Congress nor the administration in Washington is as naive as these appearances suggest. The notion that the US government might first bind itself to make the deficit vanish and then buckle down to the task of reaching that previously unattainable goal has been around since the early summer. It has gathered force since September, when the members of President Reagan's political party in the US Senate felt themselves betrayed by the President's agreement with the Democratic Speaker of the House of Representatives which had the effect of killing off the Senate Republicans' plan for squaring the circle of the budget deficit. The notion provided marvellous material for newspaper columnists with opinions on the US constitution, for it means that Congress should surrender its right to legislate how public money is spent to a person whose only qualification for public administration is the possession of a hand calculator. But now, when the administration needs to increase its power to borrow money above 2×10^{12} for the first time, the Gramm-Rudman bill (named after Republican senators from Texas and New Hampshire respectively) has inevitably attached itself to the bill that would provide the borrowing authority needed to keep the United States afloat. By now, President Reagan will probably have both his borrowing power and the threat that next year's budget will be determined not by priorities but by simple calculations of proportionality.

Basic research in the United States will be one of the early casualties. This is how that will come about. Next year's deficit has been pegged at \$144,000 million, and the administration has said that it will live within that limit. But the administration has also said that it will increase military spending by 3 per cent while not increasing taxes. Since large chunks of public spending (salaries and social security, for example) are fixed by law, the money will have to come from the government's dispensable spending, science and education included. This, no doubt, is why there is so much anguish about the preparations for the 1987 budget, due to be made public before February next year. It is hard to believe that the rising trend of research spending over the past five years will not be reversed next year, in the pursuit of a deficit of a mere \$144,000 million. But there may be worse to follow, for if the Congress and the administration fail to agree on a budget within the law, there will be *pro rata* reductions of all adjustable spending programmes. So next October, agencies such as the National Science Foundation and National Institutes of Health will be robbed of funds they had planned to spend, but

to a degree that will be known only a few days before the financial year begins. And there is an even more immediate threat; the same legislation specifies a cap for the budget deficit for the current financial year, now nearly a quarter gone. If, on 1 February next, it seems that spending will exceed \$176,000 million, which is almost certain, there will be an immediate cut across the board (which will nevertheless not exceed \$11,000 million). Will research grants be cut individually, or merely postponed? And with what effect?

The most helpful analogy of this way of conducting a great nation's financial business is the old recipe for extracting the teeth of dentist-shy children by tying a string to the tooth and to a door-handle, allowing the tooth to be extracted by the first person to open the door. In the last resort chance will be substituted for reason. It is a prescription for doing most damage to the public spending programmes which most of all depend on continuity and the pursuit of long-term objectives. It will be a great waste if the Reagan administration, with its creditable record of support for basic research over the past five years, should not put the enterprise into reverse, either in the process of meeting the targets Congress has decreed or in the inevitable ruckus about spending that is bound to erupt in 1986 (which is an election year).

Not that the objectives that the Congress had set for the government are invalid. The US budget deficit has been a literally mounting scandal for the past four years, causing endless damage in the United States and elsewhere. To cover its deficit while trying (successfully) to contain inflation, the US government has had to borrow funds that would otherwise have gone into private investment in the United States. So, until recently, the dollar has been overvalued relative to other currencies and the United States has been saddled with a deficit in its external trade numerically almost as large (\$140,000 million or so this year) as the budget deficit. As a consequence, the clamour had gone up that traditional industries being driven out of business should be protected against competition which is unfair only in the sense that it is caused by the budget deficit, and is thus artificial. As yet, the threat to world trade has been contained, largely because the administration has stoutly set its face against the erection of trade barriers, yet there is now alarming evidence that world trade is in serious trouble; OPEC cannot sell its oil, nor can the International Tin Council sustain the price of tin. So there is a danger that developing countries will be even less able to pay their debts by means of exports and that industrialized countries will further languish.

Gloom

If the gloomy forecasts that inflation has now given way to deflation should prove correct, it will then be plain that the Gramm-Rudman legislation has arrived at just the wrong time. For then, monetarists will be required to behave as if they were Keynesians, pumping money into the economy even if they have to print it, applauding budget deficits as the simplest way of curing an economic evil potentially as damaging as the inflation that seems only just to have been moderated. It seems inevitable that there must be some switch of policy along these lines long before the timetable for making the US budget deficit zero. Sadly, much damage has been done in getting this far. □

No pigs in pokes

A British dimension to the US Strategic Defense Initiative is not necessarily a bad thing.

THE trouble with the Strategic Defense Initiative (SDI) is that it means all things to all men. To Mr Reagan, it ensures immunity from other people's hostile missiles, but to Mr Gorbachev it is an abomination. Mrs Margaret Thatcher, the British Prime Minister, is somewhere in between. Through her, the British government has insisted that SDI is a research programme only, and that there is no question of deployment unless the owners of hostile missiles are consulted. Mrs Thatcher has also taken the lead in Western Europe in saying that influence of this kind requires collaboration, but only if the price is high enough.

How well does last week's agreement between the defence ministers of Britain and the United States match these good resolutions? Nobody can be sure. Virtually the only provision of the document made public is that which specifies that the substance of the agreement will be kept secret "in perpetuity". There will never be an opportunity for telling what costs, and what prizes the participants can expect. For all that can be told, the agreement may consist only of a single sheet of paper binding the participants merely to declare they have agreed to collaborate on SDI, but saying nothing else (together with the bit about perpetuity). So what should such an agreement contain? Even those who believe that Britain should not take part have an interest that the agreement should be equitable.

Technically, there are several important issues, of which the chief is whether SDI will be a stimulus to economic innovation. The argument is simple, but also simplistic. Spend money on military innovation, and you cannot fail to generate economically worthwhile innovations. So the more technical effort in British defence laboratories, the more prosperous British civil industry will become. There are two obvious objections. First, Japan, the most successful source of economic innovation, supports only a small military establishment. Second, Britain has for four decades spent conspicuously on defence research, but has been woefully inadequate at converting military into civil innovations. Whatever the secrets of last week's agreement, there is no chance that economic benefits will flow without structural changes in the relationship between military and civil research.

Worse, in British (but not American) conditions, the involvement of industry with powerful customers for knowledge (as SDI will be) can have the opposite effect; in retrospect, the dependence of the British telecommunications industry on the old public monopoly of British Telecom, far from making it competitive with free-standing industries elsewhere, actually made it harder for British companies to hold their own in world markets. At this stage, arguments about proprietary rights to inventions are academic.

So the long-term commercial benefits to Britain cannot be large unless there is structural change. Will the short-term cash (there has been talk of British organizations winning 7 per cent of the total) be of assistance? Here again, the arithmetic is clouded. If there is more money, some who might have emigrated may stay in Britain; the other side of that coin is that close acquaintance with SDI may tempt others who would have stayed in Britain to cross the Atlantic. But the most likely (and sombre) course of events is that great skill will be locked up in a programme of little economic value. The chances that people will pick up skills they never had, and will afterwards deploy them in civil applications, are small.

Technically, SDI is more likely to be a diversion than an opportunity. Politically, given the point from which the British government starts on strategic issues, it is on more sure ground. At some stage, there is bound to be an argument about the rights and wrongs of deployment. Most probably, if SDI yields anything of value to military technology (early warning is probably inevitable), there will be pressures to deploy what machines there are before the other side has been consulted. That is when

Mrs Thatcher or her political heirs will be able to cash the political cheques they will earn in the next few years. The question, and perhaps the darkest cloud over last week's agreement, is whether British governments will keep their independence and their nerve over the whole decade ahead. □

Australia's grudge

The McLelland report seems a fair complaint. What can be done?

THAT Australia should have been up in arms about the uses made by the British government of the deserts of Western Australia for testing British bombs three decades ago is natural and understandable. Last week's report on more than two years of a judicial investigation of the matter (strictly by a Royal Commission set up by the government of Australia) has failed to substantiate the more lurid tales told in evidence, but is otherwise fair. The chief recommendation, that the British government should somehow compensate Australia for the damage done, perhaps by cleaning up the radioactive mess left behind, is on the face of things a reasonable demand. But there is a danger that relations between the two governments will deteriorate into an unseemly squabble unless both of them acknowledge how much has changed, technically and in their political relations with each other, since the days when the Prime Minister of Australia, Sir Robert Menzies, was one of Sir Winston Churchill's closest buddies.

With the lapse of thirty years, it is hard fully to appreciate that even technical people could have been as naive as those in charge of the early nuclear tests about the dangers of radioactivity, both ionizing radiation produced directly from exploding fireballs and radioactive fission products or other radioactive isotopes produced indirectly, by the irradiation of material in the environment. To be sure, by 1945 there was a growing body of knowledge of the problems. The effects of X rays had been carefully studied, while the Manhattan project had thrown up a substantial understanding of the effects of external radiation by other materials, neutrons for example. The destruction of Hiroshima and Nagasaki eventually yielded crucial data about the biological effects of acute doses of external radiation. But of necessity, the effects of small doses (sustained by people some distance from the explosions) accumulated only as the years went by. So, by the time of the United States conference on the Peaceful Uses of Atomic Energy exactly thirty years ago, it was possible for the then chairman of the then US Atomic Energy Commission, Mr Lewis Strauss, to insist that there must be some kind of threshold dose of radiation below which no biological damage would be done. While Mr Strauss may have had a special flair for resisting unwelcome ideas, he was by no means untypical of those with influence in the 1950s. And only about that time did even the critics of nuclear weapons testing begin to accumulate telling evidence of the kind that eventually brought tests of nuclear weapons in the atmosphere to a halt.

The other important change that has come about in the past thirty years concerns Britain and Australia, then bound together both by the warm sense of having worked successfully together in a good cause (the Second World War) and, less easily, by the old ties of empire. It is hard now to reconstruct the familiarity of that relationship, although it seemed as natural to many Australians as it seems to have done to Menzies that the British should have been given more or less free range of the testing grounds in Australia. That the use they made of their licence may have been, by present standards, imprudent is amply demonstrated by last week's report. Much the same was happening then and earlier at the US testing grounds in the Pacific (see p. 502). The most urgent need now is that the British government should openly acknowledge the likelihood that much of Judge McLelland's argument is correct. To do that need be no shame (nor entail the A\$100 million talked of). To fail to make proper acknowledgement would be unjust, and make still more distant the relationship between Britain and Australia. □

SDI

Star wars research not up to scratch?

Victoria, British Columbia

THE US government is not rigorously applying the usual criteria for the assessment of scientific projects to all research proposals to the Strategic Defense Initiative (SDI). This is the nub of the allegations against SDI levelled by David Parnas, Landsdowne professor of computer science at the University of Victoria.

Parnas acquired a certain notoriety when, last June, he resigned from the computing panel of the SDI project, to which he had been appointed an adviser a

There's no money in crime—go for SDI contracts.

few months earlier. He has since become one of the most outspoken critics of SDI on technical grounds.

Parnas is due to give evidence to a sub-committee of the US Senate's Armed Services Committee this week. He says that the essence of his complaint will be that scientists seeking research contracts have discovered that "when the decisions are made by people who have a mission, they tend to give the money to the people who make the biggest promises".

Parnas is especially critical of those at universities who have taken SDI money while knowing that the project will not succeed. His resignation letter in June said that he did not believe that "further work by the panel will be useful; I cannot, in good conscience, accept further payment for useless effort".

To the criticism (by SDI) that the computing problems would have been less conspicuous if those responsible for them had made greater use of artificial intelligence (AI), Parnas says that he has been watching the advocates of AI for years and has remained unconvinced. "They make extremely false claims. They solve very simple problems, but when you look at them closely, you find that the methods do not generalize."

To Parnas, the chief problems confronting SDI are that it will never be possible to test the system properly, while the researchers will not be able to define the be-

haviour of the attacking missiles with sufficient clarity.

In his own field, Parnas says that software is the last part of a system to which designers pay proper attention. Although it may be easy to "get the bugs out of" the mechanical part of a system, design flaws in the software will come to light only years after it has been put into operation. Yet the task facing the SDI software will be formidable; on one estimate, the system will need no fewer than 10 million lines of code.

Parnas guesses that, in an SDI system, there will have to be a computer on board every satellite, in the first instance to process the raw data. "Even if you are going to do the computing in a centralized system, you are going to have to do some

computing on the satellites to reduce the amount of data you have to transmit." Yet it will also be necessary for the satellites to control their own sensors and some weapons.

Parnas is convinced that the software needed for SDI is so complicated that it cannot be expected to function reliably. He argues that there will have to be systems for handling the data from the sensors, and for computing the trajectories of hostile warheads, distinguishing them from decoys. Then it will also be necessary to determine the paths of retaliatory missiles, and to decide when they should be fired. "Software", says Parnas, is the glue that holds such systems together." He notes that both the Apollo Moon programme and the space shuttle have been delayed by software problems. He is not against military research programmes, and remains a consultant for the US Navy. Yet he is resentful that money should be channelled into what he considers to be the wasteful SDI programme, as well as the wasteful use of manpower and of computers that will be involved. **Bill Johnstone**

SDI

British role is still unclear

Washington

THE long-awaited agreement signed last week in London on British participation in the Strategic Defense Initiative (SDI) should allow British researchers to bid for a "significant" proportion of the \$26,000 million the Reagan administration wants to spend on the programme over its first five years, according to British officials. But despite British efforts to secure a commitment from the United States to at least \$1,500 million-worth of contracts, no guarantees of specific sums are mentioned in the agreement.

British/US scientific collaborations have in the past been marred by accusations that Britain has failed to secure adequate returns. The most contentious aspects of last week's agreement, those relating to intellectual property rights, were not made public by British Secretary of State for Defence, Michael Heseltine, and US Secretary of Defense Caspar Weinberger, and the exact terms are likely to remain secret. Instead, Weinberger and Heseltine agreed that collaboration would be as "full and fair" as national laws permitted, and that there would be the "fullest possible retention of benefits of participation".

When dealing with domestic companies, the US Department of Defense (DoD) waives its rights to patents arising from basic research that it supports, with the proviso that it will not subsequently have to pay royalties to the developers. It is unclear whether it will adopt the same position for foreign companies.

Closely related to the question of intellectual property rights is that of security

classification. While the majority of SDI contracts let so far have been classified, those originating from the SDI organization's innovative science and technology office — some 5 per cent of the total by value — are unclassified, and the director of that office, James Ionson, has said that unclassified research projects will not be classified retrospectively. US specialists caution, however, that the limits to permissible commercialization of research funded by DoD are uncertain at the best of times, and depend greatly on how strictly the Pentagon chooses to enforce particular cases.

Another problem for British companies is likely to be that DoD as a matter of deliberate policy will often divide up or "compartmentalize" different sections of strategically sensitive research for security purposes; the result is to make integrating the results of a research project difficult for the individual investigator.

British officials stress that participation in SDI research does not imply an unfettered commitment to building and deploying a ballistic missile defence; Britain says it stands by an agreement reached a year ago between Prime Minister Margaret Thatcher and President Reagan, in which the two leaders agreed that any deployment of such a system would be subject to negotiations.

British participation in SDI will be coordinated by a new SDI participation office established within the Ministry of Defence in London. Areas where collaboration is expected include architectural design studies, optical computing and electronic materials. **Tim Beardsley**

French research planning

How will the future come about?

PERHAPS the French Revolution so divided and politicized the nation that every now and again France seems to need to pray together, to demonstrate its solidarity. This is the spirit in which researchers and industrialists met at the National Colloquium on science and technology in 1982, and this was also the spirit in which the same groups met again at the end of last month, at another grand mass — one praying for the future.

The meeting, "Prospective 2005", was jointly sponsored by the Centre National de la Recherche Scientifique (CNRS) and by the Commissariat du Plan (le Plan for short), which together had spent a year on the preparations. In many ways, the meeting marked le Plan's return to the public stage. Founded after the Second World War, le Plan became famous for its planning of France's spectacular economic rebirth during the 1950s. More recently, it has been somewhat moribund, suffering an uneasy relationship with, and neglect by the socialist government until, it seems, le Plan discovered technology.

The main fruit of the discovery so far seems to have been last month's colloquium on technological France twenty years ahead. But, unfortunately for le Plan, the general feeling was that the year of study by expert groups, and the voluminous documents they presented to the colloquium, amounted to a flop.

A report on communications, for example, was described by one communicator as "arid"; no doubt he was as aware as the other participants of the tremendous political debate then (and still) raging outside on the prospect of a fifth (private) French television channel run in collaboration with Italian and British interests and the future use of the first (and French) European direct broadcasting satellite to be launched next October.

The formal documents on the future of medicine similarly failed to take much account of the potential contribution of genetic engineering, but one of the colloquium rapporteurs dismissed — with venom — the notion that microgravity (as in a space station) might be of great importance in materials processing.

The rights and wrongs of these issues are certainly arguable. The future of French television was firmly outside the meeting's terms of reference. Less glamorous techniques than genetic engineering (such as halting smoking) might have more impact on public health in 2005 than any monoclonal magic bullet. But materials processing in space does occupy a large proportion of French research ministry funds devoted to work of this kind. One aggrieved representative of French industry complained at the meeting that the research ministry's funds devoted to space-based and land-based special pro-

grammes in materials science are in the ratio 4:3 (FF80 million against FF60 million). One consequence of this vein of realism, as the French would call it, was the opposite of what might have been expected of the nation that nurtured Jules Verne: the colloquium made the future seem a little dull.

The exception was the dramatic presentation of the future of unemployment in 2005. We are moving away from a civilization of pain and labour (*civilization de la peine*), the colloquium was told, to one of *civilization de la panne* (implying breakdown), a more flexible way of working than at present. The mere labour of the workers would no longer be needed, the colloquium was told; twenty years from

now, there would be 100,000 robots at work in factories, 25 times as many as at present. Before then (ten years from now), there would be an electronic workstation on every office desk. By 2005, retraining would occupy 10 per cent of people's working hours, which would by then be reduced by a quarter. The urgent need, the conference was told, is that institutions and trades unions should worry about the career patterns of the future.

This uplifting theme evoked a sour note. The intended massive increase of education and of retraining is a policy "of the elite for the elite" according to one who should know, the director of an employment office in north Paris with 3,500 unemployed people on its books. He doubted whether ordinary people would be able to cope with what the future, even as described, would expect of them.

Robert Walgate

UK medical research

MRC defends core of excellence

UNDER continuing financial pressure, the UK Medical Research Council (MRC) intends fully to protect the best jewels in its crown, but to throw out those that are substandard. Speaking in London last week, Sir James Gowans, secretary of MRC, said that only then would it be possible for the council to afford much needed equipment for existing units, to start new units and to give proper support to university research.

One unit to be backed up to the hilt is the Laboratory of Molecular Biology at Cambridge. A search committee has been set up to find a director to replace Sydney Brenner, who will be retiring from the post by 1987 and Sir James said that the

headed by Sir Michael Stoker that is due within the next two weeks.

Although MRC is well off relative to the other British research councils, with a budget that is falling only slightly in real terms, it has such big inescapable costs — mostly permanent scientific staff — that grants to university researchers, spending on capital equipment and the number of research studentships awarded have all fallen markedly in the past two years. For example, capital equipment spending has dropped from £6 million in 1982–83 to £3 million in 1984–85. Of projects worth £4 million rated to be of high priority for which central funds were sought this year, only £2 million could be found, although some more will follow from the extra £2.5 million recently added to the science vote.

Similarly, whereas it was possible in 1982–83 for MRC to support 80 per cent of the alpha-graded grant requests from universities, the figure has now fallen to 55 per cent. Most worrying, says Gowans, is that the total number of applications has fallen from 1,200 to 950 in the same period, suggesting that the scientific community is losing hope.

Unconventional ways of funding have been used for MRC's two current major initiatives. For the Institute of Molecular Medicine in Oxford, both the Wolfson Foundation and the Edward Penley Abraham Research Fund have contributed substantially to capital costs, and the research groups within the institute will be expected to compete for grants rather than be tenured. And the Centre for Collaborative Research, which will occupy a building being vacated by the Imperial Cancer Research Fund next to the National Institute for Medical Research at Mill Hill in London, is expected rapidly to become self-financing as a result of industrial backing.

Peter Newmark

council will have "some flexibility" in the salary that can be offered, although it will not be possible to compete with US universities or industry.

On the other hand, the MRC Pneumoconiosis Unit at Penarth has been closed because the science was not good enough and the Trauma Unit in Manchester is closing because it proved impossible to find a new director of sufficient calibre. Moreover, it is rumoured that two neuroscience units will soon be closed down, while the Clinical Research Centre must be nervous about the report of a committee

Polish universities

Government admits sackings

THE Polish government has now admitted that more than seventy university and higher college rectors, proctors and deans and department heads have lost their administrative posts, almost twice as many as was first reported.

An official announcement last Friday explained that under the amendments to the Higher Education Act, passed last July, the Minister of Science and Higher Education has the right to "review" senior university staff, not only on the basis of their academic work, but also of their "civic attitude". By the end of last month, university officials whose work or "civic attitude" was unsatisfactory had to be informed that they would not be confirmed in the offices to which they had been elected before the change in the law.

The dismissals have been interpreted throughout Poland as a move to regain some of the government and party control over the universities lost during the "liberalization" of the Solidarity era. This is, to some extent, confirmed by the official announcement which stresses that universities must be run according to what it calls the "state and socialist character" of higher education. Throughout Poland, students and academics have been vocal in condemning the changes, and at least one rector not himself affected by the dismissals, Dr Kazimierz Szebiotko of the Poznan Agricultural Academy, is said to have

resigned in sympathy.

Concern has also been expressed elsewhere. In London last week, the Polish ambassador, Mr Stefan Staniszewski, was summoned to the Foreign Office for what was officially described as a "sharp" exchange of views with the Minister of State Malcolm Rifkind. Mr Rifkind warned the ambassador that the dismissals were bound to have an adverse effect on British parliamentary and public opinion, and said that they did not sit well with official Polish assurances that normalization and reconciliation were proceeding satisfactorily in Poland. Mr Staniszewski is said to have expressed surprise that the British government should interest itself in an internal Polish matter, and said that the British government should stick to its 1981 stance that internal developments in Poland were for the Polish people to settle. Mr Rifkind replied that an expression of concern did not constitute interference, but that the dismissals made the Polish government claims seem rather hollow.

Mr Staniszewski himself departed from his stance of non-interference by observing that those concerned in the changes had not lost their teaching jobs whereas in Britain thousands of university lecturers were out of work. In the Polish universities, however, there seems to be a consensus that the dismissal of the officials is only the first step.

Vera Rich

Nobel peace prize

Controversy over the winner

THE 1985 Nobel peace prize ceremony this week was surrounded by last-minute controversy over one of the two persons delegated to receive it, Dr Evgenii Chazov, Deputy Health Minister of the Soviet Union.

The prize was awarded to the organization International Physicians against Nuclear War. In October, when the prize was announced, it was stated that two officials of the organization would represent it at the ceremony in Oslo, Dr Bernard Lown from the United States and Dr Chazov from the Soviet Union. The trouble started, late in November, when it became widely realized that Dr Chazov had, in 1973, signed a letter from Soviet scientists attacking Academician Andrei Sakharov, who himself received the Nobel peace prize in 1975. Some human rights groups called for the 1985 prize to be withdrawn, and one group organized an "alternative peace prize" ceremony in honour of Dr Anatolii Koryagin, now serving a 7-year labour camp sentence for having published in *The Lancet* in 1981 a detailed study of the political misuse of psychiatry in the Soviet Union.

Dr Chazov's co-recipient, Dr Lown, has

been vocal in his defence. Dr Chazov, he says, has said nothing against Sakharov "since 1980". That was the year when the International Physicians against Nuclear War was founded, and also the year in which Dr Sakharov was exiled to Gor'kii. It is not clear which of these events (of both) Dr Lown had in mind. In fact, as recently as last week, Dr Chazov, speaking on the Norwegian ARD-Tagesthemen news programme, said that he was "not in agreement" with some of Sakharov's statements on the nuclear arms race, and quoted an unnamed US physicist to the effect that Sakharov was being made "a prawn in the cold war" and exploited "in a pharisaical manner" in pursuit of anti-communist aims.

Dr Lown, however, seems to have had considerable difficulty with his media statements. In particular, he was reported to have told the wire services that he considered it "shameful" that the US ambassador to Norway had decided not to attend the award ceremony, and then, several hours later, to have told the BBC's "World At One" programme that this was the first he had heard of the ambassador's decision.

US defence contracting

NASA chief steps aside

Washington

THE US Army's Sergeant York anti-aircraft gun, whose development was cancelled in August after \$1,800 million had been spent on it, seems more effective at damaging people than aircraft. Last week, Mr James H. Beggs, administrator of the National Aeronautics and Space Administration (NASA) for the past four years, was forced to take indefinite leave of absence after being indicted by a Los Angeles grand jury for complicity in an alleged fraud by General Dynamics on the US government.

General Dynamics, best known as the constructor of the *Trident* submarine and the F16 fighter aircraft, has been one of several military contractors in trouble with the Department of Defense over cost accounting, and was suspended from receiving US government contracts for a period earlier in the year. Mr Beggs was a vice-president of General Dynamics, and the one in charge of the company's brief involvement with the anti-aircraft gun until he moved to NASA.

This unexpected development is bound to be a setback for the agency. It seems to be agreed that the year ahead will decide how quickly, if at all, NASA secures the funds with which to build the permanent space station on which NASA has set its heart.

Against the background of a probable budget squeeze early in the new year, this is also a time when an agency cannot easily afford to lose its chief administrator for an extended period.

Both Beggs and General Dynamics hotly deny the charges levelled against them, which centre on allegations that the company, while working on a fixed-price US Army contract to make prototypes of the Sergeant York gun, charged excess costs on the project against other military contracts.

The amount involved is alleged to have been \$7.5 million in a total contract price of \$40 million. On the basis of the prototypes, the development contract was eventually awarded to the other bidder, Ford.

At no point does the Los Angeles indictment suggest that the alleged fraud was other than for the benefit of the company. Three other officials of General Dynamics have been indicted, together with the company itself. Company spokesmen have been suggesting that the origin of the charges lies in the procedures used for charging particular costs to various contracts.

The length of Beggs's absence from NASA is undetermined, but will presumably be at least as long as the time it takes for the case to come to trial.

British pharmaceuticals

Spin-off for research

THE Wellcome Foundation, the British pharmaceutical manufacturer, last week announced its best results ever. This development may have important consequences for British medical research because the company's sole shareholder, the charitable Wellcome Trust, already a substantial source of research funds, plans to sell 20 per cent of its major assets early in the new year. The higher this year's profits, the higher next year's share price is likely to be.

Wellcome's annual report for 1985 says that an increasing share of its business now derives from the United States, and that last year's profit of £121.7 million is largely accounted for by the then favourable exchange rate between the dollar and sterling. Even so, profits are up by 37 per cent over last year, and amount to 12 per cent of the turnover of £1,004 million. Thanks to aggressive marketing, the US business accounted for 45 per cent of turnover and 73 per cent of the profit during 1985. The company spent £122 million on research and development last year.

For the year ahead, the pharmaceutical business hopes to do well with innovations prompted by concern over AIDS (acquired immune deficiency syndrome). Wellcome has to decide soon whether to seek to market its diagnostic tests for AIDS in the United States; the test is one of two selected by the Public Health Service in Britain for the routine screening of all donated blood, which began a few months ago.

Through its US subsidiary, Burroughs-Wellcome, the company is also hoping to make some headway with the antiviral compound azidothymidine, otherwise known as AZT, which is said to inhibit the multiplication of HTLV-III (human T-lymphotropic virus type III) in cell cultures and to have done well in toxicity tests in human subjects. Wellcome says that the drug development process has been shortened from three years to three months in the development of AZT so far, which is a measure of the eagerness of drug houses to put an anti-AIDS drug on the market. But Wellcome is exceedingly cautious about the potential of AZT, no doubt so as to avoid embarrassment of the kind following last month's announcement from Paris of a "successful" treatment of AIDS (see *Nature* 318, 3; 1985).

The sale of 20 per cent of Wellcome's assets in January 1986 is expected to raise £300 million for the trust. The trust will then spend an extra £10 million per year on the support of permanent medical research groups in British universities (see *Nature* 317, 662; 1985), which, added to its present expenditure of £20 million, will make it the single largest supporter of such research in the United Kingdom, spending more on medical research in the uni-

versities than does Britain's Medical Research Council.

The trust is still trying to decide how to attract the best projects. Last week it announced an award to Professor Neil Brooks and Dr James McCulloch at the University of Glasgow for the study of Alzheimer's disease. The research will be

Advanced ceramics

Rush to metal/oxide composites

Boston

A NOVEL method of making ceramic metal composites, known as the lanxide process, was a major attraction at this year's autumn meeting of the Materials Research Society in Boston. The new process, rumoured for some months, was described in public for the first time by Dr Mike Newkirk of the Lanxide Corporation of Newark, Delaware. It promises new tough ceramic composites at significantly lower cost than existing methods, which tend to be expensive and produce a brittle end result.

Lanxides are formed by reaction between a molten metal and a vapour-phase oxidant, for which air will suffice. Typically, the metal has to be doped with a least two dopants — magnesium and silicon work for aluminium — and the temperature of the melt brought to within set limits (1,250°C in this example). The lanxide, in this case a coherent composite of aluminium and interconnected aluminium oxide, forms at the metal surface.

The mechanism of the reaction remains obscure. The material grows from the metal/oxidant interface towards the oxidant, and metal is transported through the growing lanxide by a process that appears not to be reliant on diffusion. The properties of the material, which can be grown in slabs an inch thick can be adjusted by altering the temperature of the melt and by depleting (or not) the reservoir of molten metal.

The microstructure, which reveals a millimetre-scale columnar grain, changes over the cross-section of the lanxide. By appropriate choice of conditions, tensile strength or toughness of an aluminium/aluminium oxide lanxide can be increased significantly above that of sintered alumina. No details of other lanxide materials were given last week, but Newkirk said that "hundreds" of inventions arising from the new technology are being patented.

Military and proprietary interest in the new materials is intense. Obvious applications include rocket and jet engines, armour plating and the Strategic Defense Initiative, where there will certainly be a demand for strong but light materials. According to Professor Rustum Roy of Pennsylvania State University, the im-

portance of the process was brought to the attention of President Reagan soon after it became apparent, and much of the development has been funded by the Defense Advanced Research Projects Agency under conditions of strict secrecy, with arms traffic regulations being invoked to restrict access of technical details to foreigners. Earlier this year, Lanxide Corporation, co-founded by Newkirk two years ago to commercialize the process, received an \$18 million cash injection from Alcan Aluminum Limited in exchange for a 42 per cent holding. Joint ventures between Lanxide and other companies are now also being negotiated.

Tim Beardsley

Bad day for Yonas

THINGS did not go too well last week for Dr Gerold Yonas, chief scientist of the Strategic Defense Initiative (SDI) Organization, when he addressed the Materials Research Society on "Materials for SDI".

Reliability of complex systems has surfaced as a potentially major problem for SDI, and half of the organization's budget is devoted to battle management systems and communications and control. But the frailty of even the most carefully staged events was emphasized when Yonas got up to speak, only to find himself completely inaudible to the audience of close on a thousand. Conference aides fussed and fumbled for a couple of minutes before it was discovered that someone had forgotten to switch on Yonas's microphone. The irony was lost on nobody.

Yonas proceeded to gallop through his usual one-hour presentation on SDI, spiced with some new references to the need for strong and light materials in, for example, space-based reflectors for lasers, and for materials with low coefficients of expansion in infrared lasers. The talk would have been better suited to an audience of high-school students or perhaps congressmen than to a technically-sophisticated group of researchers, and the applause was less than enthusiastic. After some generally hostile questions, Yonas left, perhaps wishing he had not bothered to come.

Tim Beardsley

Information technology

Britain's flagship looks for help

FLAGSHIP, an optimistic collaborative project between the British government, industry and two university departments, was launched in London last week. A £9.3 million investment is being made by the Department of Trade and Industry's Alvey programme with a consortium comprising ICL (Britain's only major computer company), Plessey, Imperial College London and Manchester University, increasing to £15.5 million for the initial three years of the project. Flagship is the long-awaited fifth-generation information processing system with many general-purpose applications. But whether the British project can keep up with Japanese and US efforts is open to question. Certainly legal squabbles over who is to reap the profits from products developed by Flagship have delayed the start of the project.

The general aim of Flagship is to evolve an architecture with sophisticated parallel hardware and "intelligent" software that will be easier for the non-technical user to operate. Imperial College has developed the software for Flagship (the Alice graph-reduction machine) and the hardware is provided by Manchester University's Dataflow machine. ICL is to develop the system at its Manchester site. The Alice prototype uses Inmos transputer chips, but ICL says that recent worries about the future of Inmos will not affect Flagship —

"we already have all the transputers we need".

The Flagship project will concentrate on declarative styles of programming, and will use Dactl, Alvey's compiler target language, which Alvey hopes will be adopted as a European standard. Flagship also uses Pisa (persistent information space architecture) for interfaces between applications, computers and data.

The Alvey programme was set up in 1983 to stimulate research on advanced information technology; its priorities are intelligent knowledge-based systems, man-machine interfaces, software engineering and very large-scale integration. The aims of fifth-generation computers were set out by Japan in 1982; such an architecture should produce computer

systems that work 1,000 times faster and handle 10,000 times more information than existing machines, as well as the "social" function of communication in a natural language rather than machine codes.

The applications of the Flagship type of system are enormous — project management, "knowledge" databases, image processing, robotics and office systems are some areas that Flagship will be seeking to develop in the next few years. The biggest threat to Britain's commercial aspirations is seen to be from the Japanese, who are putting considerable effort into advanced systems architectures. For example, Japan supports eight giant electronic corporations that make microchips, compared with Britain's single troubled company, Inmos. At Flagship's launch last week, Mr Geoffrey Pattie, minister for information technology, hinted that Britain might look for European collaboration for future stages of the project.

European Synchrotron Radiation Facility

Grenoble siting hits a snag

THE Prime Minister of France, M. Laurent Fabius, may have broken the law when he decided to site the European Synchrotron Radiation Facility (ESRF) at Grenoble rather than Strasbourg. That at least is the opinion of M. Jean Raymond, an adviser to the local government of Strasbourg, who is planning to bring the issue to a head this week. M. Fabius has only just emerged, apparently unscathed, from the trouble caused by his remark last week that he had been "troubled" by his president's reception of General Jarulewski at the Elysée Palace.

M. Raymond's case against the Prime Minister was argued at a public meeting in Strasbourg a week ago, and is based on an agreement between the national government and that of the Alsace regional council which was signed in April 1984. The national government apparently agreed to "support the candidature of Strasbourg as a site for new international organizations". It supplied a list of eligible organizations, among which ESRF was one.

One question is whether all the items on the list were to be considered for Strasbourg in the first instance, or whether they were merely examples; Raymond believes the intention was clearly the former. But the second more substantial question is whether the agreement can be legally binding whatever interpretation is correct. Raymond argues that planning laws enacted in 1982 and designed to devolve power to the French regions do indeed have the force of law. He seems to have a point when he adds that none of the procedures specified in the 1982 act for rescinding agreements between central and local governments seems to have been followed when ESRF was moved to Grenoble.

A dispute between the regional government, which belongs to the political right,

and the socialist government in Paris thus seems inevitable. M. Fabius's case would undoubtedly be stronger if the machine intended for Grenoble were already partly built. But as yet, no ground has been broken there; indeed, the government is still seeking foreign contributions towards the project. So the return of ESRF to Strasbourg is not impossible.

Robert Walgate

Satellite insurance

ARIANESPACE, the French-based company that sells space on the European space launcher Ariane, has moved quickly to offer customers insurance at reasonable cost (see *Nature* 317, 567; 1985). The company has set up a subsidiary, the Société de Réassurance des Risques Spatiales (known as S3R), which will offer users a free re-launch of a failed satellite.

S3R is designed to cover the next fifteen Ariane launches over the next five years, and will offer insurance at premiums of 10–13 per cent, compared with the 20–30 per cent being quoted unofficially by the open markets. The difference stems from S3R's sanguine view of the risks. It expects only one failure in the next fifteen Ariane launches, compared with the one-in-five risk expected by private insurers.

Even so, the new company expects to lay off some of its risks on the private re-insurance market. S3R is meant only to cover the next three years, after which it is hoped the insurance market will have been reassured by Ariane's performance.

Whether the terms now offered constitute a subsidy will be fiercely argued both by the private insurers and by those who regard Ariane as a serious competitor of the space shuttle.

Robert Walgate

UNESCO minus one

THE British government last week formally announced its resignation from UNESCO (United Nations Educational, Scientific and Cultural Organization), to the consternation of many remaining members. The £6.4 million that Britain contributed will be transferred to the British Council, Mr Timothy Raison, minister for overseas development, said last week. The government will use the money to enable more students from the developing countries to study in Britain; numbers are expected to increase from 11,000 to 12,000.

Members of other European Community countries, particularly France and West Germany, Japan and members of parliament from the three major parties in Britain, all objected strongly to Britain's decision to withdraw. Mr Amadou Mahtar M'Bow, UNESCO's director general, expressed his "deep regret" at Britain's departure.

Britain, after the departure from UNESCO by the United States last year, had demanded many reforms in the organization (see *Nature* 14 November, p.98; 5 December, p.397). Some were implemented at the recent general assembly in Sofia, but Britain felt that UNESCO had not gone far enough.

US bomb tests

Radiation tests underestimated?

Washington

THE US Department of Defense (DoD) was criticized last week by the General Accounting Office (GAO) for underestimating the exposure to radiation of 42,000 service veterans who participated in the 1946 "Operation Crossroads" atomic weapons tests at Bikini Atoll. According to GAO, the DoD's assessment, on which basis the Veterans Administration has so far rejected medical claims based on radiation exposure, may underestimate or entirely overlook significant beta exposure, while the internal alpha dose may be underestimated by a factor of 5 to 10.

The two Crossroads explosions, the first above water and the second below, were the first atmospheric weapons tests in peacetime, and radiological protection procedures were crude or non-existent. Decontamination procedures, showering and changing of clothes, for men working to clean up ships moored near the explosion, were only instituted six days after the second (and much dirtier) test, as the extent of contamination became apparent. The clean-up was eventually halted because of high radioactivity level, but only 6,300 of the 42,000 participants in Crossroads wore film badge dosimeters, and none wore badges every day.

Because records are so incomplete, DoD in 1977 asked its Defense Nuclear Agency to reconstruct exposures by extrapolation from known cases. The agency's conclusion, published last year, was that 93 per cent of those involved received exposures of less than 0.5 rem, and that all received less than 1.7 rem (the permitted total for radiation workers in the United States today is 5 rem per year). But GAO has identified several respects in which it believes DoD's analysis is in error.

Most doubt centres on the accuracy and interpretation of film badges. The badges did not work in the way expected, possibly

because of the effect of humidity, and GAO believes beta exposures could as a result have been seriously underestimated: 100 per cent error can be expected at the lower end of the range, for which DoD made no allowance. GAO also finds that personnel decontamination and protection procedures assumed by DoD were not in effect (immediately after the tests) or were widely ignored; in none of the photographs of the clean-up operation are the men wearing protective clothing.

DoD has formally disagreed with many of GAO's conclusion, but GAO retorts that DoD's comments are based on incor-

rect and unsupported statements and misinterpreted documents. GAO's recommendation is that DoD be required to revise its estimates to take account of the sources of error now identified. If the revisions are carried out and GAO's conclusions validated, the implications could be great for the 500 veterans' disability claims relating to Crossroads, as well as to the many thousands of others relating to different tests; the Veterans Administration has already indicated that it wants to extend GAO's findings. The GAO report, which was requested by Senator Alan Cranston of the Senate Veterans' Affairs Committee, will doubtless form the background to what may be expected to be stormy congressional hearings in the near future.

Tim Beardsley

Computers

Putting back the clock

Berkeley, California

CONVENTIONS held sacred for decades by the designers of computer hardware and software are being seriously challenged by computer researchers at the University of California, Berkeley. At the fore of the challenge is a new development in microchip technology which has simplified the design of the electronics needed for computers and jettisoned redundant and laborious machine coding.

That part of the Berkeley revolution began about five years ago, but its proponents believe the change is at last about to be accepted in the industry despite the controversy the ideas have generated and the hostility they have provoked. According to David Patterson, an associate professor of the Computer Science Division at Berkeley, and one of the creators of the new machines, "1986 will be the year when we see what happens".

The new computer designs were arrived at by inspecting a VAX minicomputer and identifying many machine code instructions that were never used in most com-

putational exercises. In that inspection, 304 such instructions were reduced to one tenth that number. So was born the Berkeley computer concept, called Reduced Instruction Set Computers (RISC).

The RISC machines turned the clock back in computer design. The evolution of computers — mainframe, mini and the micro designs in the 1970s and 1980s — used volumes of complicated instructions (the basic code programming the machines) and relied more and more on intricate and faster microelectronics to control that complex structure. A computer evolved within the computer, controlling these arrays of instruction codes, most of which were never used.

Berkeley's idea was to minimize the coded instructions needed to operate the machine and, at the same time, to design a simpler microchip. The RISC microchip made at Berkeley, the hub of the new machine, now has over 41,000 transistors and 60 32-bit registers. It can be fabricated on silicon down to a gate size of 4 μm with a speed of 500 ns per instruction.

Berkeley's research has been matched by that of others at Stanford University, IBM at Yorktown Heights and now at Hewlett Packard. Says Patterson, "Hewlett Packard is going to base its whole next generation on these ideas". IBM is rumoured to be developing workstations on the same principles.

Patterson is confident that RISC is a forward step despite its apparent resort to simpler technology. "Many people find this to be a ridiculously bad idea. It's a de-evolution of computer design... a dangerous concept. Shouldn't be talked about". Patterson and his Berkeley team are continuing to talk about it, and are developing the concept even further to see if the RISC machines can be further enhanced for the scientific and academic use of computers. One such application to be pursued is the use of RISC for artificial intelligence.

Bill Johnstone

Soviets admit AIDS cases

THE Soviet Union has now admitted that AIDS (acquired immune deficiency syndrome) has reached the Soviet Union. Interviewed in the newspaper *Sovetskaya Kultura*, Dr Viktor Zhandrov, a leading Soviet virologist, denied the growing rumours that there are "numerous" cases of AIDS in the Soviet Union but acknowledged that there had been an "insignificant number of cases" reported.

This comes less than two months after Soviet denials that there were any cases of AIDS in the Soviet Union (see *Nature* 317, 659; 1985).

Dr Zhandrov's article is less polemic in tone than previous Soviet statements on the disease, which stressed its connection in the West with drug addiction (relatively

rare in the Soviet Union) and homosexuality (which is illegal).

He stressed, moreover, that the disease seems to have originated in central African monkeys. This is in marked contrast to a recent trend in the Soviet media to attribute AIDS to United States bacteriological warfare experiments; although much of this reporting seems to be anecdotal (for example, that in Kenya AIDS has developed in proximity to a US base), not all of it has been directed at Third World audiences. In particular, on 30 October, *Literaturnaya Gazeta* quoted the Indian popular daily, *The Patriot*, to the effect that AIDS was developed in the United States at Fort Detrick as a weapon against the black and homosexual communities. Vera Rich

Japanese research

Private investment still growing

Tokyo

RESEARCH in Japan's private sector is booming as never before. Expenditure has grown 12 per cent this year (eight times as fast as the government science budget) with 78 per cent of the nation's research funds now coming from industry. These figures set the scene for the Science and Technology Agency (STA)'s white paper, *New developments in R & D and the age of cooperation*, which was approved by the cabinet last Friday.

The aim of the white paper is not so much to sing the praises of industry as to point out some weaknesses that in part stem from such a high reliance on the private sector and to suggest ways of correcting them. One new bill aimed at increasing cooperative research is all ready to go before the Diet.

Overall investment in research and development is growing proportionately faster than the economy and has now reached 2.8 per cent of national income, not far short of the 3 per cent goal set by the government. Virtually all companies involved in high-technology industries — electronics, telecommunications and biotechnology — are spending at least 8 per cent of their sales on research and development.

The other side of the coin is the relative weakness of government and university research and failure of budgets to keep up with inflation for several years running. This means that there are weaknesses in areas that industry cannot easily tackle; those requiring large-scale interdisciplinary cooperation and those requiring long-term cooperation for an uncertain pay-off.

Lack of government impetus partly reflects low government expenditure, and partly low levels of collaboration between the universities, government research institutes and industry. This is a perennial problem, but the need to get something done seems more urgent than before. Almost all advanced nations are pushing hard in the same high-technology fields. And as the report neatly points out, they are all adopting very similar science policies; everywhere industrial investment is being increased through similar packages of tax incentives and policy designed to spur cooperation between different research fields.

The white paper identifies key problems and, not surprisingly given that the paper is the work of a government agency, suggests solutions that nearly all involve increased expenditure at government laboratories. Two of the problems are interrelated; *per capita* expenditure on basic research is still low compared with Western nations, and basic research in public laboratories is insufficiently creative. The first is a problem of money. Unfortunately whatever STA might believe is correct,

there is little chance that the government will increase basic research funding when it has a fiscal deficit proportionately larger than that of the United States. The second is more a problem of organization and in particular failure to provide young researchers with the freedom to put their talents properly to work. The problem is now to be taken up by the Council for Science and Technology — Japan's highest advisory body chaired by the Prime Minister. A few days ago, the council agreed to a wide-ranging debate on the operational management of the public research institutes.

A third problem seems to stem from a feeling that anything the West is doing Japan should be doing too, in this case its giant research projects such as the Strategic Defense Initiative (SDI) and the emerging Eureka programme which might produce a quantum jump in technological level. There is nothing really new on the horizon, to follow large-scale projects such as the development of the

"bullet" train and automatic telephone switching gear. STA officials suggested that international cooperative projects in cancer research, fusion energy, giant accelerators and space platforms might all be candidates for the development of completely new technologies. But there is little prospect of a major publicly-funded Japanese research initiative under current budgetary constraints.

Positive action is at hand to deal with the fourth problem, that of encouraging cooperative research between industry, government and the universities. The need for some form of cooperative research is obvious to industry: in the past few years, there has been a striking rise in joint research performed abroad. Growth in tie-ups with domestic institutions has been much more sluggish. A new bill to be introduced by the cabinet in March and intended to clear the Diet by the summer should remove at least the legal restraints on cooperation between the public and the private sectors. The bill will also make it easier to carry out cooperative research with foreign companies and tackle problems of patent rights. **Alun Anderson**

CEGB

Acid rain storm from Norway

"UNBALANCED and biased", Norwegian Ministry of the Environment official Jan Thompson said of the British Central Electricity Generating Board (CEGB) video "Acid Rain". The Norwegians pulled few punches at the press conference they had called in London on Monday of this week to give their response to the recently released film. Thompson continued "the views put forward in the CEGB film are obsolete and dangerous . . . and will in the long run strain the relationship between the two countries. A cynical attitude was expressed".

The 20-minute video, widely distributed throughout the United Kingdom, purports to present a balanced and objective view of the acid rain issue, and concludes that the effects on the environment of acid precipitation may have been overestimated and that there is considerable doubt in the scientific community that the widely reported deaths of fish and forests in Europe are caused by acid rain. In addition to CEGB personnel, the film uses interviews with Norwegian, Swedish and German scientists, and was partly shot in Norway. The Norwegians say that neither their environmental authorities nor major research institutes were notified. They also claim that there was considerable bias in the selection of persons interviewed, and that interviews were cut so as to present a distorted view of opinions expressed. At least one scientist, Swede Hans Hultberg, is understood to have protested strongly against the editing of his comments.

The seriousness with which the Norwe-

gians are treating the affair can be judged from the fact that in addition to a report on the video sent to CEGB, a letter from the Norwegian Prime Minister, Kaare Willoch, has been delivered to Mrs Margaret Thatcher. The subject of acid rain was prominent in a meeting between the two late last month. In carefully chosen words, Jan Thompson said "we are not talking about a diplomatic protest".

The Norwegian scientists at the conference — Professor Seip and Dr Muniz from the University of Oslo and Mr Dovland from the Norwegian Institute for Air Research — presented detailed evidence, some new but much previously published, to support their case that some 15–30 per cent of the sulphur deposition in southern Norway originates in the United Kingdom. They argue that the recent reductions in emissions from Britain result only in fine tuning when used in long-range pollutant transport models. The claim is not that stopping emissions from Britain alone would solve the problem, but that concerted European action is needed to stop this "chemical war", as Muniz described it.

The Norwegians claimed that the natural environment is being seriously damaged and that it is disturbing that acid precipitation can be so lightly dismissed by CEGB on the grounds, among others, that 100 per cent scientific certainty has not yet been achieved. Borrowing a symbol for the *Bulletin of the Atomic Scientists*, Seip showed an acid rain clock; the hands stood at five minutes to midnight.

Peter Gambles

Dioxin exposure at Monsanto

SIR—Hay and Silbergeld urge a re-examination of the information about workers exposed to dioxin at the Monsanto plant in Nitro, West Virginia¹. They do not actually challenge the conclusions of two studies that there were no excesses of cancer or heart disease deaths among dioxin-exposed workers, but they convey the impression that the studies are seriously flawed.

In particular, they draw attention to the fact that four men classified as exposed to dioxin in one paper were classified as not exposed in the other. The first paper, which classified the men as exposed, defined exposure by the presence or history of chloracne², a disease known to be associated with dioxin. The other, which classified the men as not exposed, defined exposure by a history of work assignments in processes involving dioxin³. Neither measure is perfect, and they are not congruent. Although the differing classifications are disquieting, at least three of the cancer deaths are probably independent of dioxin exposure. Those three were lung cancer deaths among smokers; the fourth was from Hodgkin's disease, for which there is no strong evidence for association with dioxin. If the differing classifications for the four men are enough to destroy the conclusions reached by the authors of the studies, that analysis should be developed by Hay and Silbergeld.

From Monsanto records that they do not further identify, Hay and Silbergeld state that 19 workers who would be classified as exposed and who died from circulatory disease or cancer were not included in the second mortality study. They do not provide information about how they determined the men's exposure, the number of unexposed men who died from the same causes during the same time period, nor when the men died. If they died before 1955, they would not have been included in the study, which, because of records limitations, was restricted to men who left the company after that time. A telephone call to the authors might have clarified the reason that those men were not included. Whatever the outcome of such a call, it would not have contributed to the aura of conspiracy achieved by the sentence "No reason is given for not including those cases".

Workers exposed as a result of the 1949 explosion at Nitro are generally considered to have been more heavily exposed than workers involved in usual processes at the plant. Hay and Silbergeld, referring to a 1953 study⁴, contend that the basis for that conclusion was more severe chloracne among the accident-exposed workers. While chloracne was worse among those workers, a panoply of other health complaints — fatigue, incapacitating aches and pains, libido and potency problems — was also elevated, lending cre-

dence to the contention that accident-exposed workers were more heavily exposed. I am uncertain what point Hay and Silbergeld want to make as they labour over the conjecture that there may have been no differences in exposure levels, but they follow that effort with criticism of the authors of the mortality studies for separating the two groups of men in their studies. The criticism is misplaced. While one paper² was limited to workers involved in the aftermath of the 1949 accident, the other¹ included all hourly workers who terminated their employment after 1955, whether or not involved in the 1949 accident.

Having found no evidence of excess cancer in the Nitro workers, Hay and Silbergeld turn the idea of dose-response relationships on its head and suggest that diseases such as cancer "may be expected" in people exposed to "lower and more chronic exposures". References offered in support of that idea are two books that contain data both suggesting and not suggesting a link between dioxin and human cancer and two papers associating cancer in herbicide sprayers with dioxin. The herbicide sprayers characterized as chronically exposed were exposed only during one or two months a year⁵, for a median total exposure time of 42 days. Studies of another population, which included more than 1,500 sprayers who had been exposed for at least 12 months, found no cancer excess⁶. Furthermore, some Nitro employees worked for years in production processes that involved dioxin and some, not exposed through the explosion, developed chloracne⁷. Those men were surely chronically exposed to dioxin, many were included in the Zack and Gaffey¹ study, and there is no cancer excess. The hypothesis that low-level, intermittent exposures bear more risk than higher-level exposures requires substantiation.

Hay and Silbergeld's penultimate paragraph refers to a health survey⁸ as support of a possible connection between dioxin and an "excess of cardiovascular-related deaths". The health survey presents no new data about mortality; it does refer to an excess of cardiovascular deaths in Monsanto workers already reported by Zack and Gaffey¹. An editorial that accompanied publication of the health survey suggested that the health survey might include some evidence for an excess of myocardial infarctions (not deaths) among men who had had chloracne⁷, but that the appropriate analysis is wanting. Finally, the mortality study that reported the excess of cardiovascular-related deaths in Monsanto workers found no difference in death rates from the cause between workers exposed and not exposed to dioxin¹, and the number of cardiovascular deaths among chloracne-stricken workers was less than 75 per cent of the

expected number⁸.

Hay and Silbergeld criticize studies that use chloracne as the criterion of exposure. They are on firm ground when they say that the disease is a dependent variable of exposure and that epidemiological studies usually use some independent measure, such as work histories, as the criterion for exposure. However, they raise no criticism of the health survey⁸ for depending on chloracne as a measure of exposure. Apparently, a double standard is used, studies that cannot be interpreted to show excess deaths being held to a higher one.

In Hay and Silbergeld's words, "the epidemiological picture at Monsanto remains confused". The picture is more unclear than anyone would desire, but it is not quite so confused as they have it. Their letter shows that it is possible to locate flaws and select studies to support an argument that dioxin is possibly a scourge. Equally, it is possible to read the literature and arrive at a cautious conclusion that dioxin has not caused early death and cancer in heavily exposed workers. That conclusion, which is widely accepted⁸ and draws on information from dozens of studies done in the past decade, might lift some anxiety from people who have been environmentally exposed to lower levels of dioxin.

AIDS

SIR—Misinformation on acquired immune deficiency syndrome (AIDS) continues to abound and Ian Davidson's comment (*Nature* 317, 666; 1985) is another example.

It is wrong on two counts: (1) It is perfectly possible to be promiscuous and have little risk of contracting AIDS, providing one avoids certain high-risk sexual practices; (2) Non-promiscuity does not guarantee that one will not contract AIDS. Certain groups are still at risk, for example wives of gay or bisexual men, and intravenous drug abusers.

I do not know if chastity has replaced death as the "great unmentionable", but fiction seems to have replaced fact when it comes to the truth about AIDS.

Whose rings around Neptune?

What seems to be an authentic and interesting discovery of an incomplete ring around the planet Neptune seems certain to be published piecemeal for lack of agreement among those concerned.

READERS will be puzzled by the tentative explanation of the partial ring around Neptune provided on page 544 of this issue by Dr J. Lissauer of the University of California, Berkeley, chiefly because they have no reason to believe that there is such a structure around this distant planet. Surely, readers will ask, it will be time enough for Dr Lissauer to produce his explanation when there is evidence to suggest the need for one. And why should this apparently pointless explanation begin with the flat unsubstantiated declaration that "an incomplete arc system has recently been discovered around Neptune"?

Dr Lissauer should not be judged too harshly. Evidence for a partial ring system around Neptune does indeed exist. Roughly six months ago, an article giving a full and interesting account of the discovery was submitted to *Nature* for publication, was accepted for publication and would long since have been published had not those responsible for the collection of the evidence fallen out over the wording of the paper. All the authors have throughout expressed distress at being caught up in such a childish business yet have been unable to reconcile their differences.

What follows is an account of the circumstances leading to this sad state of affairs, from which two lessons may be learned. First, there may be occasions when pride takes precedence over the principle that science is an open process, in which publication is a duty owed to the rest of the community. Second, there are some outside the community who will ask whether science can be as deserving of public support as journals such as this repeatedly insist.

One of the prime movers in the discovery of the ring around Neptune appears to have been Professor André Brahic, from the University of Paris and the Observatoire de Paris, who has a long-standing interest in planetary ring systems. Brahic was the first author (among eight) of a manuscript "Occultation detection of a neptunian ring-like arc" which reached the *Nature* office at the end of May this year. The other authors quoted were W.B. Hubbard and F. Vilas from the University of Arizona, who have access to the Inter-American Observatory at Cerro Tololo in Chile, together with L.R. Elicer, a member of the observatory's staff; two colleagues of Brahic's from Paris, B. Sicardy and F. Roques; Patrice Bouchet, a staff member at the European Southern

Observatory (ESO), also in Chile, and two European astronomers, Jean Manfroid from the University of Liège and R. Haefner from the Max Planck Institute of Astrophysics at Munich.

The origins of the dispute among the authors can be traced to the night of 22 July 1984, when there was a near-occultation of Neptune of a bright red star in Sagittarius, then visible from the two Chilean observatories. Brahic and his colleagues in Paris, who seem long to have suspected that Neptune may have a ring system, seem to have taken the initiative in drawing attention to this event. Ironically, Brahic had applied for observing time at ESO on the night in question, but had been given time to look at the rings of Uranus instead. Robbed of this chance, and with the good offices of Bouchet, Brahic seems at second-hand to have persuaded Haefner and Manfroid, the intended occupants of two telescopes at ESO, to turn away from their planned project to look at the occultation by Neptune instead.

In the event, Haefner and Manfroid found that there was indeed a brief second-long interruption of the infrared radiation from the distant star as it crossed an invisible circular orbit roughly 77,000 km nearly 3.0 radii from the centre of Neptune. One curious feature of the observations was that there was no corresponding dip in the radiation intensity as the distant star crossed the same circular orbit at its supposed second interception of it, whence the notion that, if there is a ring around Neptune, it is incomplete.

A similar sequence of events was found at Cerro Tololo, 100 km away in the Andes. Elicer began his observations later in the night, just a few minutes before the expected near-occultation and in some haste, to judge from the circumstance that it is not known what filter had been interposed in one of the two infrared channels. But the results are decisive and essentially the same as those found at the ESO site. Again there was a single interruption of the radiation, lasting about a second but no corresponding dip at the supposed second interception.

It is common-ground that these observations can only mean that there is absorbing material in one part of a supposedly circular orbit about Neptune, but that the material does not extend uniformly around the orbit. Brahic has rightly all along insisted that only coordinated

observations at different sites can lend credibility to such fleeting events. (Clouds, electrical disturbances or passing flocks of birds could be held responsible for a brief interruption of radiation at a single site.) But with a well coordinated pair of observations in hand, Brahic was able to go back to previous attempts to find occulting material around Neptune. The pair of Andean observations last July, from sites separated by 100 km, show that the absorbing material around Neptune must be at least 100 km in extent. The time for which radiation was interrupted suggests an object 15 km across.

So, now there is an interesting and quite novel phenomenon to be explained, a partial planetary ring. If it had been possible to publish the data on which the inference is based, people other than Lissauer would have been stimulated to bend their energies to this interesting problem. But why are the data still under lock and key?

Several things have gone wrong. The ESO observers, Haefner and Manfroid, have been offended by what they consider to have been unfair publicity overwhelming their contributions, a press release from the University of Arizona relayed in semi-popular journals such as *Sky and Telescope*, for example. An article by Brahic in *La Recherche* last June seems to have given particular offence, although all the intended authors of the original *Nature* manuscript are duly listed in the margin. Haefner and Manfroid have published their data in the German-language journal *Stern und Weltraum*.

Much of the difficulty turns on the question of who "owns" the data collected at ESO, the observers who collected it or Brahic who drew attention to the occultation and to whom the data tapes were sent by prior arrangement? And what is to be done with data which, as in this case, are more interesting when combined with other people's than when published on their own?

The saddest feature of this development is that, whoever owns some of the data, there is a sense in which they belong to the scientific community as a whole. The upshot is that an important and even urgent set of data will not now be published quickly, as it should have been. The reputation of astronomers for good sense will have been undermined. Even the reputation of science as a whole will have been damaged — let us hope not irreparably.

John Maddox

Forensic science

DNA fingerprinting in matters of family and crime

from Barbara E. Dodd

IT HAS long been the ambition of the forensic scientist to be able to identify the origin of blood and body-fluid stains with the same degree of certainty as fingerprints. And the ability to settle cases of doubtful paternity with absolute certainty in every case would be equally welcome. The arrival of DNA fingerprinting — particularly as developed by Alec Jeffreys and colleagues at Leicester University^{1,2}, whose latest paper is on page 577 of this issue³ — is a big step towards the forensic scientist's goal in both areas.

As so often happens, the technique has arisen from research that was not aimed specifically at solving practical problems. Jeffreys had been working on the short 'minisatellite' sequence of DNA in an intron of the human myoglobin gene. Using the now familiar methods of Southern blotting and DNA hybridization he found that the myoglobin minisatellite detected other human minisatellites, some of which are highly polymorphic. The common features of these minisatellites have been identified by sequencing, and cloned DNA probes, based on tandem repeats of the core sequences, have been used to detect simultaneously several highly variable genetic loci in the human genome. It is this extreme variability in the pattern of minisatellites detected by the probes,

together with the stable inheritance in the usual mendelian manner of an individual's pattern, that is the basis of DNA fingerprinting.

In this issue of *Nature*, Jeffreys with P. Gill and D.J. Werrett of the Home Office Forensic Science Service report promising progress in applying DNA fingerprinting to blood stains, semen stains and hair roots, showing that DNA fingerprints obtained from these sources are always identical to those of the individuals from whom the material originated. Especially rewarding are the results of DNA fingerprints of sperm nuclei and their potential for the identification of rapists. There are conventional genetic markers in semen and semen stains are frequently contaminated with vaginal fluid, so that the origin of any markers present is difficult or well-nigh impossible to trace. Gill *et al.* have managed to isolate sperm nuclei free from vaginal contamination and have obtained a DNA fingerprint that is the same as the donor of the sperm. Thus it should be possible to match a DNA fingerprint of sperm from, for example, a stain on a victim's clothing with that of blood or sperm from a suspect rapist. A chance match is virtually eliminated because its probability is calculated to be of the order of 3×10^{-11} , or even less if more than one

probe is used. The technique, however, has yet to be tested and assessed for application in actual casework. How easily DNA fingerprinting can be assimilated in a routine crime laboratory remains to be established.

Other work is in progress on the feasibility of using DNA polymorphisms in the examination of blood and semen stains. M. Baird and colleagues of Lifecode Corp., New York reported at the 11th International Congress of the Society for Forensic Haematogenetics in Copenhagen last August. They have used probes that recognize two highly polymorphic DNA sequences to show that DNA recovered from blood stains up to three years old can be used for identification purposes and that the DNA fingerprints of sperm recovered from female volunteers after sexual activity, when freed of female cells, is identical to that of the male partner's sperm.

The numerous blood-group polymorphisms that are currently applied to cases of doubtful parentage (usually doubtful paternity) already go far towards excluding every man wrongly named as father of a child. Exclusion of paternity is established by showing the absence in the putative father of one or more blood-group gene products, which, in the child, are seen to be paternally inherited. A range of polymorphic systems are investigated independently of each other by relatively simple procedures in which the gene products are disclosed by agglutination, cytotoxicity tests or some form of electrophoresis. The table shows how a combination of polymorphisms can approach the ability to exclude all false fathers. Moreover, the calculated probability of paternity for unexcluded men, virtually all of whom will be true fathers, is likely to be significantly in favour of their paternity.

Even so, DNA fingerprinting with the probes developed by Jeffreys has the potential to exceed the efficiency of the conventional systems because there are good grounds for anticipating that definitive answers, not only those excluding paternity but also for pinpointing the true father, will be obtained in every case. But it is in resolving problems of family relationships in which putative parents are closely related to each other that DNA fingerprinting has particular advantages over presently used systems. This has already been demonstrated by Jeffreys *et al.*³; the problem was that of a Ghanaian boy who was refused entry into Britain because the authorities were not satisfied that the woman claiming him as her son was in fact his mother. Analysis of a range of systems similar to those in the table showed that the alleged mother and son were almost certainly related (probability of non-relationship 0.01) but the conventional tests were not capable of determining whether the woman was the boy's mother or aunt. DNA fingerprinting established that the mother-son rel-

Unique garnets in diamonds

Enlarged view of a diamond, from the Monastery Mine kimberlite pipe in South Africa, that contains two garnet inclusions (on the right-hand side, with dark shadows surrounding them) and four jadeitic clinopyroxene inclusions. The garnets are the first of natural occurrence to contain pyroxene in solid solution, which indicates an unusually deep origin for the diamonds. This discovery and its implications for mantle structure are described by R.O. Moore and J.J. Gurney on page 553 of this issue.

ationship was correct because the minisatellites detected by the probes are so hypervariable that the chance of a sister of the alleged mother sharing all the maternal specific bands of the child was 6×10^{-6} .

DNA polymorphisms have also been investigated with respect to US paternity problems, as reported by I. Balazs at the Copenhagen congress. He and his colleagues at Lifecode Corp. have examined DNA polymorphism associated with two genetic loci in more than 100 paternity cases and have shown that their probes produce an exclusion probability similar to HLA (see table). So far their results have not been presented in court. The American Association of Blood Banks committee on parentage testing has studied the implications of paternity testing by DNA and has issued guidelines. These include the need to validate DNA probes by extensive family and population testing before they are used in parentage testing; the estimation of gene frequency and mutation rate for the genes being detected; the inclusion of duplicate gels and blots; and, at least for the present, parallel testing with accepted systems.

Although DNA fingerprinting as developed by the Jeffreys team requires but a single series of manipulations to disclose a richer variety of polymorphisms than shown in the table, the process is very labour-intensive and needs both meticulous expertise and much experience in the reading and interpretation of the bands that appear in the final autoradiographs. And since the outcome in human terms is likely to be far reaching and since no confirmatory tests using other independent systems are possible, it is surely essential to duplicate each test. A two-tier procedure may develop, beginning with a range of conventional systems and proceeding to DNA fingerprinting in selected cases.

One can foresee that through the energy of molecular biologists, probes suit-

able for appropriation by forensic scientists will proliferate while techniques for DNA fingerprinting may become simpler. Excitement concerning the application of DNA fingerprinting to forensic science has to be tempered by the realization that much assessment remains to be done. If this proceeds satisfactorily it will be difficult to disagree with the prediction of Gill *et al.* that DNA fingerprinting will revolutionize forensic biology. □

mass of the asteroid zone would have remained reasonably constant throughout most of the life of the Solar System, the main loss having occurred as a result of the primordial process that stirred up the zone — possibly perturbations by a proto-Jupiter. This stirring changed the low interparticle velocities at which accretion could take place into much higher impact velocities which resulted simply in collisional fragmentation.

One way of discriminating between these two possibilities is to look at the collisional evolution of the present asteroid belt and to wind this back to see if one gets a reasonable initial population or not. If the population is large the first process is sufficient. The second process would indicate that the asteroid zone has had a low mass ever since the growth of proto-Jupiter. This has significant implications for the degree to which asteroidal spins have been modified by collisions and for the amount of fragmentation that asteroids have suffered.

Consider the observational constraints. Davis *et al.*³ note that Vesta (the fourth largest asteroid, diameter 480 km) has a largely intact basaltic crust, indicating that it has not been shattered during the pre-primordial period and that the number of bodies capable of breaking up Vesta must be low. A significant number of asteroids are members of families having similar orbits and having been produced by the disruption of a single parent, generally thought to have a diameter about 200 to 300 km^{4,5}. The fact that the families persist indicates that collisions are rare.

A third, less strict, constraint comes from collision modelling³. The frequency of collisions at 5 km s⁻¹ between asteroids of, say, 100-km and 500-km diameter is quite well known but the outcome of the collisions is not. In laboratory studies, collision energies reach around 10¹ ergs, which is less than 10⁻²¹ of the kinetic energy of a body with a 100-km diameter.

Farinella *et al.*² turn to the rotational properties of asteroids as the fourth constraint. About one third of the asteroids in the 200–300-km-diameter range seem to have elongated shape, indicated by large light-curve amplitudes and rapid spins. If this was induced by collisions there must have been about five times as many asteroids larger than 65 km in the initial (post-primordial) population than there are now. A similar conclusion is reached by Davis and colleagues³.

The history of the asteroid zone is still somewhat vague. Greenberg *et al.*⁶ found that it would take about 10⁵–10⁶ years to accrete Ceres if there was initially a total rock mass of about the mass of the Earth, all in the form of 1-km bodies. Then something must intervene to terminate the accretion. Maybe it was orbital stirring by proto-Jupiter. If so, Jupiter has to accrete very quickly, more quickly than the asteroids, and one is still left with the problem that the stirring process itself takes about

Solar System

Missing mass in the asteroid zone

from David W. Hughes

LIKE the Cassini division in Saturn's rings, there is a division in the Solar System, at the asteroid zone. Both these divisions indicate regions of high mass depletion. At present, the asteroid belt between the orbits of Mars and Jupiter contains an observed¹ mass of about 5×10^{24} g, about one thousandth the mass of the Earth. If the distribution of mass in the proto-planetary solar nebula were reasonably uniform there would have originally been sufficient rocky material in that zone to form a planet or planetary core of at least the same mass as the Earth. What has happened to this mass? Farinella, Paolicchi & Zappalà² suggest two alternatives —

either there has been continued gradual loss of mass or the main mass was lost primordially and little has been lost since.

The gradual process would result from asteroids breaking up as they collide together at a mean speed of around 5 km s⁻¹. Most of the debris has speeds well above the escape velocities of the two colliding asteroids and so move off into the zone. The Poynting–Robertson effect, that is the symmetrical re-radiation of absorbed unidirectional solar radiation, retards the dust, causing it to spiral in towards the Sun. Over the age of the Solar System this has depleted the asteroid population. In the second process, the

10^6 years. The orchestration of this process has to be finely tuned. If Jupiter formed too early, premature stirring would have prevented the accretion of large Ceres-type asteroids. If Jupiter formed too late, accretion in the asteroid belt would have continued for too long and there would now be a planet there. It was probably close run — if Ceres were about twice its present size, it would accrete even at impact velocities of 5 km s^{-1} .

Another suggestion⁷ is that accretion stopped and the asteroid velocities were increased by secular resonances sweeping through the zone. These were caused by mass loss from the Sun, this mass being dissipated in the solar nebula during the Sun's T-Tauri phase. Unfortunately, for this to work, the T-Tauri phase would have to be exceedingly active and to have lasted for about 10^4 years.

Whichever velocity-increasing process we choose, it still has to explain how the original mass of the zone (one Earth mass) was reduced to the post-primordial mass, which was five times greater than it is now. Explaining the present state of the asteroids and their origin is still a major task in Solar System science. □

Cell biology

Traffic control and structural proteins in the eukaryotic nucleus

from Larry Gerace

ALTHOUGH RNA and proteins are exchanged continuously between the nucleus and cytoplasm in most eukaryotic cells, these two compartments each maintain a distinctive macromolecular composition. The nuclear envelope, the double membrane structure that forms the boundary of the nucleus, is thought to be a major regulator of these differences. Results discussed at a recent meeting* and in a number of publications augur a new period of progress for understanding the regulation of nucleocytoplasmic traffic, as well as the molecular organization of the nuclear envelope and lamina.

Protein import

Molecules are translocated across the nuclear envelope through proteinaceous channels called nuclear pore complexes (see the figure), which are probably the major regulatory sites for nucleocytoplasmic transport. The pore complex has an elaborate architecture that has been characterized by three-dimensional reconstruction from electron micrographs¹. Whereas it contains a mass that may exceed $25 - 50 \times 10^6$ daltons, almost nothing is known about its polypeptide composition. From microinjection studies, it is known that these proteins that are much more concentrated in the nucleus than the cytoplasm ('karyophilic' proteins) possess information in their mature polypeptide structure that is responsible for their accumulation in the nucleus^{2,3}. Since the pore complex seems to contain an aqueous channel with a functional diameter of about 10 nm (ref. 4 and R. Peters, Max

Planck Institute for Biophysics, Frankfurt), the rapid *in vivo* uptake of small (relative molecular mass, M_r , less than about 20,000 – 40,000) globular karyophilic proteins by the nucleus can, in theory, be explained by passive diffusion through the pore complex followed by intranuclear binding. The size of larger macromolecules, including many proteins and RNAs, would severely restrict their passive diffusion, and their translocation across the nuclear envelope may require a mediated-transport mechanism⁵.

Considerable effort is now being focused on identifying the signals that direct some proteins into the nucleus. A karyophilic protein that has proved to be a good model for studying mediated transport is nucleoplasmin, a 165 M_r pentameric molecule. Using limited proteolytic digestion, it has been determined⁶ that the nucleoplasmin monomer has a discrete 10 M_r 'tail' that contains the information mediating the selective nuclear uptake of this protein (R. Laskey, Cambridge University). In a striking experiment⁶, injection of nucleoplasmin-coated gold particles into the cytoplasm of frog oocytes has been shown to result in rapid nuclear uptake through the pore complex of particles with diameters as large as 20 nm (C. Feldherr, University of Florida, Gainesville). This suggests that the signal in nucleoplasmin causes the pore complex to become a 'gated' structure.

Recombinant DNA procedures have precisely defined the nuclear localization signal in the simian virus 40 T antigen^{7,8}, another large (94 M_r) karyophilic protein. A short sequence of the T antigen molecule (amino acids 126 – 132) is both suffi-

cient and necessary for the nuclear localization of this protein, and if this sequence is experimentally attached to large proteins that are normally cytoplasmic, it can retarget them to the nucleus (A. Smith, Integrated Genetics). Because a similar sequence is found in other viral nuclear proteins, it may be a prototype for one class of nuclear localization signal. However, as shown for the yeast MAT $\alpha 2$ protein, two distinct sequences on different regions of the same polypeptide can each be sufficient for nuclear uptake (ref. 9 and M. Hall, University of California, San Francisco).

The key issue to be addressed at this point is the nature of the cellular structures that recognize the protein signals for nuclear accumulation. Are they part of the nuclear pore complex or are they binding sites (chromatin or otherwise) within the nucleus? When the T antigen is expressed in cells of the alga *Acetabularia*, it also becomes concentrated in the nucleus (G. Neuhaus, Max Planck Institute for Cell Biology, Ladenburg), suggesting strong phylogenetic conservation of the nuclear uptake apparatus for this protein.

An interesting mechanism that is used by cells to regulate import of nuclear proteins has come to light from developmental studies with *Xenopus*. The proteins that are complexed with U2 RNA to form a small nuclear ribonucleoprotein particle (snRNP) are stockpiled in the cytoplasm of *Xenopus* oocytes in the absence of associated RNA, and only accumulate in the nuclei of embryos after transcription of the genes for U2 RNA starts at the mid-blastula stage of development¹⁰. Microinjection of U2 RNA into oocytes induces assembly of these U2-binding proteins into snRNP, which then migrate into the nucleus.

Diagram of the major structural components of the nuclear envelope, consisting of inner and outer nuclear membranes that are joined at the pore complexes, proteinaceous supramolecular structures that provide channels for molecular movement between the nucleus and cytoplasm. The outer nuclear membrane frequently has ribosomes attached and is structurally continuous with the rough and smooth endoplasmic reticulum. The nuclear lamina, a filamentous protein meshwork lining the nucleoplasmic surface of the nuclear envelope, probably provides an anchoring site at the nuclear periphery for interphase chromosomes.

*The Workshop on Nucleocytoplasmic Transport was held in Heidelberg, FRG, 26 – 28 September, 1985.

Mutant forms of U2 RNA that are not assembled into normal snRNP do not cause nuclear accumulation of the same proteins (ref. 11 and I. Mattaj, University of Basel). This indicates that karyophilic 'domains' are generated by RNP assembly, perhaps by conformational change. A variation on this mechanism may explain how certain proteins that are initially present in the nucleus of *Xenopus* oocytes become cytoplasmic during early cleavage stages of embryogenesis, and re-enter nuclei only at precisely defined periods later in development¹².

Encouraging progress was reported on the development of cell-free systems to study nuclear uptake of large proteins. Starting with isolated DNA or sperm chromatin and extracts of *Xenopus* eggs, several groups have assembled nuclei *in vitro* based on previous procedures^{13,14} which can accumulate nucleoplasmin (T. Burglin, University of Basel), nucleoplasmin-coated gold particles (R. Laskey) or endogenous karyophilic proteins of oocyte nuclei (C. Dreyer, Max Planck Institute for Developmental Biology Tübingen). Uptake of nucleoplasmin requires ATP both as *in vivo* as well as *in vitro* (T. Burglin), which is consistent with the operation of an active transport mechanism. Cell-free systems should offer a powerful approach for studying nucleocytoplasmic transport, particularly when immunological probes to the nuclear pore complex become available.

Lamina revealed

The nuclear lamina is a supramolecular assembly that lines the inner surface of the nuclear envelope and may both regulate nuclear envelope structure and anchor interphase chromosomes at the nuclear periphery¹⁵. In cells of several higher eukaryotes, the lamina consists mainly of a small number of related 'lamin' polypeptides. At least in *Xenopus*, these proteins are coded by a developmentally regulated gene family¹⁶, and the major lamins found in germ cells are distinct from the lamins of many somatic cells (G. Krohne, German Cancer Research Centre, Heidelberg).

Three discrete 60–70 *M_r* lamins (A, B and C) are present in typical mammalian somatic cells. The first amino-acid sequences of lamin A (G. Blobel, Rockefeller University) and, independently, of both lamins A and C¹⁷ have recently been deduced from human cDNA clones. Interestingly, a region of about 300 amino acids near the amino terminus of the lamins possesses striking sequence homology (greater than 80 per cent in certain regions) with the canonical 300-amino-acid, coiled-coil, alpha-helical rod domain that characterizes all intermediate filament proteins. A large domain with little alpha helix is predicted to occur at the carboxy terminus of the lamins. Electron microscopy in my laboratory (Cohn, J. & Gerace, L. in preparation)

shows that the three lamins from rat liver (which are apparently dimers) each contains a globular head attached to an approximately 50 nm rod-like tail. The latter bears close resemblance to the alpha-helical rod of intermediate filament subunits. Together with a recent demonstration that the lamina of *Xenopus* oocytes consists of filaments with a diameter of 8–10 nm arranged in a regular near-tetragonal lattice (Buhle, L. & Aebi, U. in preparation), these data indicate that the lamins constitute a hitherto unrecognized class of intermediate filament proteins.

Unlike many intermediate filament proteins of the cytoplasm, the lamins undergo total structural reorganization during mitosis in mammalian cells, when they are reversibly depolymerized to a 4–5S form by a process that may involve lamin hyperphosphorylation^{18,19}. An attractive possibility is that reversible disassembly of the lamina regulates the disassembly and reconstruction of the nuclear envelope that occurs during mitosis in higher eukaryotes. In support of this notion, I reported that removal (by immunoadsorption) of the disassembled lamins from a cell-free nuclear envelope assembly system results in strong inhibition of subsequent nuclear envelope formation. Mitotic-like disassembly of isolated nuclei can be induced by extracts from *Xenopus* eggs arrested in metaphase^{19,20}. (J. Newport, University of California, San Diego) suggesting that purification of lamina disassembly factors is feasible. Thus analysis of lamina disassembly may ultimately shed light on the biochemical regulation of mitotic prophase which, in one intriguing scenario²¹, may involve a phosphorylation cascade.

Only the lamina of higher eukaryotes has been characterized biochemically, but

it is also present in at least some lower eukaryotic organisms; indeed, it was first described structurally in *Amoeba proteus*. It is conceivable that the lamina emerged early during eukaryotic evolution, perhaps to carry out the functions of anchoring chromatin to the nuclear envelope and regulating nuclear envelope growth. The lamins may therefore represent an ancient class of intermediate filament proteins. Although the last in the current line of intermediate filament proteins to be recognized, they are certainly not the least interesting. □

Palaeoclimatology

Cycles in the Precambrian

from A. Barrie Pittock

CLAIMS for the influence of sunspot cycles on the weather are highly controversial^{1–3}, so clear evidence for such an influence is an exciting prospect. Our best source of information is a series of periglacial varves in deposits from lakes in Australia. These varves are layers of silt laid down annually in a lake below the outlet of a glacier. They were first documented in 1981 by Williams⁴ from layering observed in a short section of exposed rock at Pichi Richi Pass in the Flinders Ranges. On page 523 of this issue G.E. Williams and C.P. Sonett present data from several drill cores giving a continuous stratigraphic sequence spanning some 19,000 'annual' layers⁵ which provides overwhelming statistical evidence that such cyclical activity really existed over a long period in the geological past.

Ever since sunspot cycles were first documented by Heinrich Schwabe in 1844, the possibility that they influence weather and climate has fascinated amateur and professional meteorologists^{6,7}. Claims for solar cycles in meteorological data have usually not been strong enough to overcome the variance in the data or to be obvious in visual inspection of time-series plots — the exceptions have in general been found to be spurious. Numerous small and marginally significant cycles have been proposed as the result of the statistical massaging of large quantities of meteorological data but most of these have again proved to be either spurious or at best controversial. Indeed, the noted Russian meteorologist A.S. Monin has characterized the field as one that is remarkable for "successful experi-

ments in autosuggestion"¹⁰.

The cyclical appearance of the varve sequence from Pichi Richi Pass is neither weak nor statistically marginal. Rather, it is visually obvious, and indeed dominates the total variance in the time series. The analysis by Williams and Sonett shows an impressive series of periodicities, including a basic cycle of approximately 12 'years', with alternating thick and thin cycles, and longer-term rhythmic fluctuations in the period every 13 cycles. Spectral analysis reveals a harmonic series with a fundamental period consisting of about 26.1 of the 12-'year' cycles and higher harmonics at 13.1, 8.8, 6.6 and 5.3 cycles.

Although the evidence for cycles in the varve sequence is overwhelming, there are problems concerning any interpretation of its physical significance. It is difficult to imagine any other explanation for the layered deposits than that of an annual meltwater cycle but the authors put 'years' in quotation marks, presumably to indicate that they have nothing more than circumstantial evidence for the annual origin of the layers. Similarly, the identification of the cyclical appearance with cycles of solar activity is largely circumstantial; we have no direct evidence for the cyclic behaviour of solar activity some 680 million years ago, so correlation of varve cycles with solar activity can only be hypothetical. Indeed, the authors imply that in future papers they will use information derived from the varve sequence to help with modelling solar behaviour — a procedure that would introduce a strong element of circularity into the argument.

Williams and Sonett interpret the varve sequence as indicating that increases in solar activity caused corresponding increases in climatic temperature, resulting

in greater annual meltwater discharge and the deposition of thicker varves. This is not consistent with a direct relationship between solar irradiance and surface temperature, since satellite measurements indicate that at times of increased solar activity, as indicated by sunspots, there is a slight decrease in solar irradiance¹¹. Of course, temperature at a particular locality on the Earth may be influenced by topographic or other local effects and so may not vary directly with fluctuations in solar irradiance.

Perhaps the biggest question posed by the varve sequence is why cycles should be so obvious in rocks about 680 million years old, when they are not strongly in evidence in the modern record. Williams and Sonett cite the existence of "a relatively weak solar signal" in recent varves from Skilak Lake in Alaska¹² but if this is the best evidence for the influence of solar cycles that can be found in recent times it leaves much to be explained. □

100 years ago

THE Government of Tasmania are making arrangements upon a large scale for naturalising lobsters, crabs, turbot, brill, and other European fishes in the waters of that country. The various consignments will be shipped at Plymouth, and transported through the medium of the steamship companies trading between London and Hobart. An exhaustive report has been published by the Government of Tasmania, setting forth the objects in view, and giving suggestions for carrying them into effect. The report adds that while the achievement of the acclimatisation of European fishes would lay the foundation of new and very valuable fishing industries in Tasmania, it might also prove a highly remunerative commercial enterprise to the shipping firms under whose auspices the operations will be conducted. Applications have been made for the supplies of fish, which have been satisfactorily responded to. Special tanks are being prepared in order to provide for the necessities of the fish *en route*.

From *Nature* **33** 137, 10 December, 1885.

are associated with the activation of *c-myc* disrupt its regulation? One possibility is that they place *c-myc* under the control of a constitutively active gene enhancer so that it is no longer responsive to the normal cellular controls. This is consistent with the finding that the normal *c-myc* allele in tumour cells containing one activated *c-myc* gene is almost always silent^{6,9}.

An alternative possibility is based on highly suggestive evidence implicating the 5' exon of the cellular gene in its regulation. This exon, which is not translated, is missing from the *v-myc* oncogene that is found in some tumour viruses and is very often lost from the cellular gene as a result of the rearrangements in tumour cells. This has led to the proposal¹⁰ that *c-myc* is under negative regulation acting on the 5' end of the gene or its flanking sequences through the binding of a repressor protein. The experiments of Adams *et al.*, however, now show that the activation of *c-myc* is almost certainly independent of the presence or absence of 5' sequences; while the most recent evidence on the normal regulation of the gene suggests that the 5' exon may be important not in the control of *c-myc* transcription but in its post-transcriptional regulation.

The evidence that *c-myc* is normally transcriptionally regulated comes from measurements of *c-myc* mRNA. The induction of cell proliferation by mitogens dramatically increases *c-myc* mRNA levels², while the cessation of cell proliferation that accompanies differentiation leads to an equally dramatic reduction¹¹. These changes were initially assumed to be in the transcription rate of the gene. However, although a rapid induction of *c-myc* transcription is found in serum-stimulated fibroblasts¹², the 3–4 fold increase is not sufficient to account for the 20–40 fold increase in mRNA level. Furthermore, after a transient increase, the rate of transcription returns to the pre-induction level while the cytoplasmic RNA level remains high.

Oncogenes

Regulation and activation of *c-myc*

from Michael D. Cole

THE regulation of the *c-myc* oncogene and its role in the cancerous transformation of cells have been among the most widely studied and controversial subjects in the study of the molecular basis of cancer. This interest has been stimulated largely by the discovery that *c-myc* genes that have been activated by a variety of mechanisms (reviewed in ref. 1) are characteristic of a very wide range of tumours. Since the expression of *c-myc* is also characteristic of normal proliferating cells, however², it has become clear that in order to understand the nature of the abnormal activation of *c-myc* in tumour cells it is essential to understand how it is normally regulated. The paper by Adams *et al.* on page 533 of this issue³ provides important insight into the mechanism of abnormal *c-myc* activation and a number of recent studies have revealed an unexpected

complexity in the normal regulation of *c-myc* expression.

Two of the possible mechanisms of *c-myc* activation can now be dismissed. First, it is clear that the levels of *c-myc* messenger RNA are no higher in normal proliferating cells than in tumour cells, so that activation is not caused by overexpression⁴. Second, the expression of *c-myc* is constant throughout the cell cycle in normal cells⁵, so earlier suggestions that the gene is cell-cycle regulated in normal but not in tumour cells are not borne out. This has led to the alternative suggestion that activation involves the loss or disruption of control elements that enable the normal gene to be switched off when the cell enters the quiescent, non-proliferating state. The question then becomes, how do the chromosomal rearrangements and retroviral insertions that

More recently it has been established that the major cause of rapid changes in *c-myc* mRNA levels is a modification in post-transcriptional RNA stability. The levels of *c-myc* mRNA decrease rapidly both in lymphoblasts treated with interferon¹³ and in teratocarcinoma cells induced to differentiate with chemicals¹⁴. This occurs without any change in the rate of transcription, possibly because of a substantial decrease in the already short half-life of *c-myc* mRNA¹⁵. An increase in mRNA levels without a change in transcription rate is also seen in secondary lung fibroblasts¹⁶. In the light of recent evidence for a role for 5'-untranslated sequences in posttranscriptional regulation, it seems possible that the untranslated first exon of *c-myc* is the major target for destabilization or transport of the transcript. Post-transcriptional regulation at the level of RNA turnover therefore seems to account for much of the modulation of *c-myc* expression. These findings, however, still do not account for *c-myc* activation by the many proviral insertions and translocations that do not affect *c-myc* RNA structure.

Adams *et al.*³ have addressed this problem using transgenic mice carrying different configurations of normal *c-myc* or *c-myc* genes linked to enhancer sequences from immunoglobulin genes. The results are quite striking and provide an elegant demonstration of the transforming potential of activated *c-myc* genes. Injection of *c-myc* genes joined to either the immunoglobulin heavy-chain or light-chain enhancers led to the induction of multifocal lymphomas in 90 per cent of the mice, while intact or truncated normal *c-myc* genes (without enhancers) produced no neoplastic disease. These findings are analogous to those of Stewart *et al.*¹⁷ in which a *c-myc* gene linked to a 'long terminal repeat' sequence of the mouse mammary tumour virus was shown to potentiate mammary carcinomas. In both studies, a tissue-specific control element apparently induces high levels of *c-myc* expression leading to a heritable susceptibility to tumours. Adams *et al.* clearly demonstrate that enhancement or transcriptional activation of *c-myc* is necessary to induce its oncogenic potential, while neither the alteration of its chromosomal position nor its truncation are sufficient for activation. However, this study does not provide an explanation of the mechanism of activation of *c-myc* transcription in the majority of Burkitt lymphomas and mouse plasmacytomas, where the immunoglobulin enhancer and other sequences that are known to control immunoglobulin gene expression are not present on the chromosome containing the *c-myc* coding exons and thus cannot influence the expression of the translocated gene. Presumably there is some unidentified transcription-activating sequence or change in chromatin configuration in these other cases.

By analysing not only *c-myc* expression

but also immunoglobulin rearrangements, Adams *et al.* obtained important additional information. First, the majority of the tumours (which were of both pre-B and B-cell stages) had a distinct set of rearranged immunoglobulin genes, which indicates that the tumours were clonal. Because the presence of the immunoglobulin-enhancer-linked *c-myc* gene in the germ line should lead to high levels of *c-myc* expression in all lymphocytes, this result suggests that a second event may be required to generate a fully transformed cell.

Furthermore, Adams *et al.* find that, whereas the enhancer-linked *c-myc* gene is expressed in the tumours, the endogenous *c-myc* gene is not. This makes the induced tumours analogous to natural tumours with transcriptionally activated *c-myc* genes, such as plasmacytomas^{18,19} and Burkitt lymphomas^{8,9}. In the light of the transcriptional and post-transcriptional control of *c-myc* expression discussed above, it will be very interesting to learn at what level the endogenous gene is down regulated. Adams *et al.* argue that the lack of endogenous *c-myc* expression is consistent with an autoregulation control model, in which expression of the activated allele suppresses the expression of the germ-line gene. However, as the authors note, they cannot exclude the possibility that the transformed B cells in their study arose from a cell in which the endogenous *c-myc* gene is not normally expressed. Furthermore, autoregulation is not consistent with observations of expression of the endogenous *c-myc* gene in some of the mammary carcinomas induced by *c-myc* linked to the 'long terminal repeat' sequences of mouse mammary tumour virus¹⁸, nor with the effects of introducing a constitutively expressed *c-myc* gene into fibroblast lines that are already expressing *c-myc*; in this case, again, the introduced gene does not affect the expression or regulation of the

Long-running experiments (III)

A dry pile has driven this electric bell since sometime before 1840 when it was re-set up in Oxford University's Clarendon laboratory. The clapper draws about 1 nA as it oscillates between the terminals at a speed which declines with humidity. Occasionally humidity stops the movement, which starts again spontaneously. It is not known what the piles are made of. More details in *European Journal of Physics* 5, 193; 1984, which invites "accounts of other experiments that call for patience on the part of the recorder".

endogenous gene¹⁸.

Is it possible that the 'second event' that seems to be required for transformation normally turns off the *c-myc* gene in a manner analogous to that seen in terminal differentiation, and that DNA rearrangements or proviral enhancers prevent this down regulation? Despite the progress that has been made in understanding the regulation of this complex and interesting oncogene, clearly many challenging questions are still unanswered. □

Mathematics

Classical continued fractals

from Ian Stewart

CONTINUED fractions are classical: they provide 'best possible' rational approximations to real numbers, expressed in the form $\alpha = 1/(a + 1/(b + 1/(c + 1/ \dots)))$, usually written as $[a, b, c, \dots]$ for simplicity. Their main use is in number theory. Fractals are of much more modern vintage. They are geometrical objects with structure on all scales. The name was coined by their inventor, Benoit Mandelbrot, to reflect their 'infinitely crinkled' shape. They are applied to irregular behaviour and form in nature.

Can two such disparate ideas usefully be combined? Indeed they can. Jenny Harrison of the University of California at Berkeley has announced progress on a baffling problem known as the Seifert conjecture based on what she calls continued fractals. The proof is sketched in *Bulletin of the American Mathematical Society* 13, 147; 1985; full details will appear elsewhere.

The celebrated 'hairy ball' theorem states that it is impossible to comb a hairy ball smooth. More precisely, any smooth vector field on a two-dimensional sphere must have a fixed point. In consequence, any smooth dynamical system whose state space is topologically a two-dimensional sphere must have at least one steady state. On the other hand, a hairy torus can easily be combed smooth, so dynamics on a torus can have no steady states at all. Such results have far-reaching consequences: for example they justify the choice of tori, rather than spheres, for magnetic bottles in experimental fusion reactors.

But what if the state space is a three-dimensional sphere? First we must explain how such an object can be visualized. The circle, a one-dimensional sphere, can be obtained from a line by adding a 'point at infinity' which is considered as lying at both ends, so that the line plus this point curls up into a circle. Similarly the 2-sphere can be thought of as a plane, plus a single point at infinity, lying at both ends of every line in the plane. The 'horizon circle' of the plane is squashed down to this single point; and much as a bag can be closed by tightening a loop around the top, the plane curls up to give a sphere. For a 3-sphere, just add a single point at infinity to three-dimensional space. To

visualize a smooth combing of the 3-sphere, we imagine a family of smooth curves through 3-space, taking care that it behaves suitably 'near infinity'.

It is not hard to find ways to comb a hairy 3-sphere smoothly, with no fixed points. Other special features tend to appear, however, notably places where the hairs form a closed loop. Is there a way to comb a 3-sphere that has no fixed points and no loops? In 1950, Herbert Seifert conjectured that there is not or, more precisely, that every smooth vector field on

Example of a continued fractal (redrawn from Harrison, J. *Bulletin of the American Mathematical Society* 13, 147; 1985).

the 3-sphere has either a fixed point or a closed integral curve. At first, very little progress was made on this fundamental problem, because nobody knew where to start.

To describe the known results we must address the question of how smooth is 'smooth'? The degree of smoothness of a curve is measured by how many times it can be differentiated. To qualify as 'smooth' it must certainly have a tangent everywhere (be once differentiable). If the position of that tangent also varies smoothly, the curve is twice differentiable, and so on. The smoothest curves are infinitely differentiable. A fancier definition lets the degree r of differentiability be fractional, indeed real, as well as integral.

In 1971, Paul Schweizer (*Annals Mathematica* 100, 386; 1971) showed that the Seifert conjecture is false in the once-differentiable case. So for a degree of differentiability r somewhere between 1 and ∞ , there is a switch from false to true (unless, as may be the case, it is always false). The question is, where? In her thesis under Colin Rourke at Warwick University, Harrison showed that the switch is at a value $r > 2$. Her new work, which uses similar methods, improves this to $r \approx 3$, pushing current techniques somewhere near their limit.

The starting point of her method is a

deceptively simple example of discrete dynamics. Take a circle, select a real number α between 0 and 1, and define a transformation T of the circle by rotating it through the angle $2\pi\alpha$. Then, under iteration of this transformation, the behaviour of points is highly sensitive to the degree of irrationality of α . Specifically, suppose α has continued fraction $[a, b, c, \dots]$, then the smaller that the entries a, b, c, \dots are, the more irrational is α .

When the rotation α is rational, every point on the circle is periodic under iteration of T . That is, if T is performed sufficiently often, every point ends up exactly where it started. If α becomes irrational, this periodicity starts to break up. For highly irrational α , such as the golden number $[1, 1, 1, 1, \dots]$, the iterates under T are evenly spread over the circle. For 'almost rational' numbers, like the Liouville number $[1, 2, 3, 3^3, \dots]$, the points tend to clump together during long sequences of iteration. Thus there is a strong link between the dynamics of T and the continued fraction of α .

There are well known techniques for constructing flows on the 3-sphere from transformations such as T , and the central question is to determine how the degree of differentiability of the resulting flow depends on the degree of irrationality of α . The falsity of the Seifert conjecture unless $r > 2$ comes from taking $\alpha = [4, 4, 4, \dots] = \sqrt{5} - 2$. Can other choices of α lead to smoother flows?

It is here that continued fractals enter. Harrison describes a geometric way to visualize the continued fraction of α , by 'unfolding' the sequence of iterates of a point under the rotation T . This leads to a curve whose geometric structure determines arithmetical properties of the continued fraction. The curve is a fractal, and its geometric fine structure corresponds to delicate arithmetical properties, making it possible to visualize the way in which α is approximated by rationals, and to apply geometric reasoning. The improved value $r \approx 3$ arises by taking $\alpha = [N, N, N, \dots]$ for large and even values of N , and by exploiting the interplay between dynamics, geometry and arithmetic. It is a vivid display of the unity of mathematics.

Meanwhile, the general Seifert conjecture remains as enigmatic as ever. Conceivably it is false even in the infinitely differentiable case. There seems little chance that current techniques can lead to a general counter-example. Harrison's methods break down for r larger than 3, leading her to suggest that it is, at $r = 3$, where the conjecture turns into a theorem. However, no proofs exist for any r, ∞ included; other considerations suggest that a proof (if indeed the conjecture is ever true) must overcome formidable technical obstacles. We may have a long wait for the complete answer. □

Ian Stewart is at the Mathematics Institute, University of Warwick, Coventry CV4 7AI, UK.

Errata

Throughout A.M.C. Sengor's article "East Asian tectonic collage" (7 November, p.16) the term "Indosinian" should replace "Indonesian", which was inadvertently substituted during editing.

In Michael Brown's article "Tectonics of metamorphism" (28 November, p.314), the wrong photomicrograph was used to illustrate Fig.2.

Another reason for saving Sakharov

SIR—I believe it is crucial in our attempts to rescue Andrei Sakharov to re-emphasize Sakharov's scientific legacy to the scientific community at large and to Soviet officials in particular. Studying recently an early paper on gravitation theory by Sakharov¹, I realized that this work not only provides a new way of looking at gravity, but also gives us a new weapon in the battle for Sakharov's life. The paper, which describes the possible connection between gravitation and vacuum fluctuations, has been referred to in a number of major textbooks²⁻⁴. My own investigations have given me an even higher opinion of this seminal paper.

I have been studying the influence of a suggested inhomogeneity in zero-point vacuum fluctuations on free particle motion and have come to the conclusion^{5,6} that in the general case the particle world-lines become geodesics of a Riemannian geometry. So I was able to appreciate Sakharov's main suggestion of a direct connection between the vacuum fluctuations and gravity (that is, Riemannian geometry of spacetime). In the appropriate sense, Sakharov obtains the Hilbert Lagrangian of general relativity. As a result the Einstein equations acquire the meaning of connection between an inhomogeneity in the vacuum fluctuations and the distribution of matter. Some formal difficulties in the development of Sakharov's concept are removed by the recently derived covariant description of gravitational energy.

I believe that Sakharov's concept may resolve the 60-year confrontation between quantum field theory approaches to gravity and Einstein's general relativity, after hundreds of futile attempts to bridge this gap. Once some formal difficulties are removed, I anticipate the development of the physics of vacuum fluctuations as a fundamental branch of science with many applications. Hence I believe that historically Sakharov's name will be among the most illustrious names in science. Like Evariste Galois, another genius of the highest originality, Sakharov chose the way dictated by his moral self-obligation and this deprived him of the opportunity to advance many of his ideas. Like Galois, he gave only a short synopsis of his concept. I believe that the concept will steadily increase in importance to science, as did Galois' contribution.

Hence I perceive a new starting point in our efforts to save Sakharov's life. His humanitarian activities have been completely rejected by Soviet authorities as part of the dangerous "bourgeois ideology" with which they claim no conciliation is possible. They do not think that Sakharov's role in the creation of Soviet nuclear weapons is worthy of reward or respect in the West. He is not considered as a head of

some scientific school inside the Soviet Union or abroad. So, to Soviet authorities, Sakharov is nothing but a Western tool of the cold war. They assume that he will be forgotten in the West as soon as he is out of sight. Hence, from their point of view, Sakharov may safely be ignored. Perhaps the new Soviet leaders will rectify this situation when they realize that his scientific legacy will not be forgotten by history and that Sakharov's persecution will be recalled in every physics textbook.

It is important to make it clear to the Soviet authorities (and perhaps to some of us also) that Sakharov is likely to be seen as the founder of a new fundamental branch of physics which may find wide application. I believe that the best way to advance this understanding is the rapid development of Sakharov's concept and its broad explanation. My belief is that the investment of money and intellectual resources in Sakharov's concept are completely justified by the expected scientific results. But there is an additional justification. The rescue of Sakharov is our ticket of admission to the human race.

Ocean thermal response in man-made climatic change

SIR—John Woods has raised¹ important issues concerning the dynamic response of ocean circulation to anthropogenically imposed changes in atmospheric CO₂ level. The full implications of the physical characteristics he presented have potentially serious environmental policy consequences beyond those discussed in his paper. The delay in ocean-atmospheric temperature equilibration due to the ocean's thermal mass following the introduction of man-made infrared-absorbing trace gases into the atmosphere implies a slower rise in global climatic warming than given by calculations that omit oceanic effects. The time it would take to reach the conventional measure of a significantly hazardous environmental condition (a global temperature rise of about 3°C, which corresponds to doubling of atmospheric CO₂ concentrations to about 600 p.p.m.v.) can thereby be lengthened by from 20 to 100 years².

Woods suggests that such a delay in temperature rise will ease the potential for traumatic climate change by providing extra time for initiation of measures to reduce climatic warming, such as the

accelerated development of nuclear in place of fossil energy. But this likely will not be the course of events. Rather, it is more probable that the needed remedial actions will be delayed until the observed climate change can be unequivocally identified with atmospheric CO₂ growth, by which time its concentration could have risen above a value whose ultimate equilibrium climate effect would be calamitous. From this perspective, thermal inertia of the oceans introduces a type of irreversibility which is obviously of major importance for policy, since global temperatures will continue rising even after a decision to drastically reduce fossil fuel use has been implemented.

Scientists' response to this dilemma is naturally to suggest that predictions, rather than observations of temperature change, be used as the basis for action. But this requires hard political decisions which are made more difficult by the acknowledged lack of understanding and quantifiability of the physical phenomena concerning climatic change and its impacts. How to properly bring the relevant but uncertain scientific information into the decision-making process, is important, and attention is starting to be paid to this type of need^{3,4}.

Before we conclude that existence of long thermal ocean inertia lags inevitably results in the major irreversibility dilemma presented above, we should point out a revision in the usual viewpoint that is needed in order to properly address the physics of the problem. The ocean transient response is normally described in terms of an e-folding time for approach to thermal equilibrium — setting atmospheric CO₂ level to be constant. However, from a policy viewpoint we need to follow the approach to a steady state following elimination of CO₂ emissions. All current carbon cycle models predict only a modest fall off rate of CO₂ levels following such a step⁵, but these probably do not allow for the involvement of deeper ocean layers that results in the extended e-folding times we have quoted. In fact, it seems intuitively clear that stronger coupling to the deep ocean implies a larger short-term oceanic sink for CO₂ deposition, and hence a faster fall of atmospheric CO₂ concentration following reduction of CO₂ emissions. If this qualitative surmise is true (and an analysis of it has yet to be made), the irreversibility feature of the policy issue we have raised may not be as severe as it seems at first glance.

Misuse of statistics in social sciences

SIR—Two letters, one from Van Valen¹, the other from O'Quigley and Baudoin², have warned against the indiscriminate use of null hypothesis testing and the confusion of level of significance with scientific certainty. The situation is worse even than they make it seem, at least in the social sciences.

As Van Valen points out, R.A. Fisher developed the analysis of variance not for hypothesis testing but to aid scientific questioning. Instead it is used in the social sciences to come to scientifically irrelevant decisions about null hypotheses. My alpha (the level at which I reject the null hypothesis), cautious person that I am, is always one in a million. Yours is one in ten. We both live by the rules. You get a lot of significant results (or almost so, or highly so); I get none. Who is right scientifically?

Guttman³ argues that hypothesis testing as used in the social sciences is, strictly speaking, anti-scientific. Science is about the accumulation of information and testing by replication. Hypothesis testing is used to dodge replication and come to immediate decisions. Yet one test of significance leaves indeterminate the probability of the outcome of the next test on a new sample. In other words tests of significance are not cumulative and do not remove the need to replicate. The result is a landscape dotted with isolated studies forming no pattern and making no collective sense. Guttman also points out what is obvious on reflection, that simultaneous *F* tests on rows, columns, interactions and so on, routine in the social sciences and built into packages such as SPSS, encounter the same problem that simultaneous tests do; they are not independent. The same error flutter that makes one contrast improbable can affect another. The logic of hypothesis testing for any other than the one-way analysis of variance is flawed.

The Neyman–Pearson statistical tools are framed in terms of a loss function: the money or resources that a decision will cost. They are designed to minimize losses in gambling, farming, industry and war. It was gamblers who first demanded probability theory and agriculturists who adopted inferential statistics. Their common problem was the need to make decisions under risk. Social scientists, faced with difficult experimental problems, took up hypothesis testing *faute de mieux* to make progress rapidly and to lend their endeavours the appearance if not the reality of scientific respectability. It is in fact irrelevant to science which is concerned with making sense, not conserving resources.

The bankruptcy of programmes of research based on the crutch of the *F* test is revealed by the choice of the null hypothesis. It is almost always that a correlation or a mean difference is zero. If knowledge were accumulating the incumbent hypothesis would hardly ever be that of no correlation or no effect. Yet this is what is tested routinely, as if all that had gone before counted for nought. It is correct to be dubious about the claims of little old ladies to tell by taste how cups of tea were poured, milk first or second. We can calculate probabilities and find them out, just as we can detect fudging, by Mendel and by Burt. The hypothesis of no effect is the correct one for improbable claims, of psychokinesis or water divining, for example. But it is not correct when we have a body of knowledge to draw on and a theory designed to predict not just that something will happen but what and how much.

The fault does not lie with statisticians. Their job is to tell us how to do statistics, not science. It is scientists who have to work out how to do science. By misunderstanding the scientific use of statistical tools social scientists have created a situation every bit as bad as Guttman says it is. Puttering along, making the same old mistakes, will in the end bring the whole enterprise into disrepute.

No to new photosynthetically active radiation units

SIR—In response to R.A. Lewin (*Nature* 316, 582; 1985), who proposes a new unit to measure photosynthetically active radiation, certain misconceptions should be dispelled. The photosynthetically active photon flux density (PPFD) is the quantity of photons incident on a unit area per unit time. It is not, as claimed, light intensity which is the luminous flux emitted by a point source into a unit solid angle (SI unit, cd), nor is it uniquely PAR (photosynthetically active radiation) which is commonly used for the radiant power (400–700nm) incident on a unit area per unit time (SI unit, Wm^{-2}).

Communication between ecophysiologists has been greatly aided by the adoption of SI units. A particular advance has been the use of PPFD (units: $\mu\text{mol m}^{-2} \text{s}^{-1}$). This unit is consistent with those of O_2 , CO_2 and H_2O fluxes, greatly simplifying the calculation of derived parameters such as quantum efficiency of efficiency of water use.

There are limitations to the use of PPFD. Density is confusing for a flux through a unit area rather than volume. The term is biased to land plants being

limited to the photosynthetically active wavelengths (400–700nm). However, the 'alb', the new unit proposed by Lewin, solves none of these problems and only adds to the confusion.

Lewin also complains that PPFD requires the use of the Greek letter, μ , which is awkward to type. Awkward as it may be, modern scientific word-processing packages can easily solve this problem. In any case, SI derived units are composed of base units, thus the 'alb' would be $\text{mol m}^{-2} \text{s}^{-1}$, and avoidance of negative exponents, abhorred by Lewin, would require the use of the ' μalb '. Does the author object similarly to μg and μm ? Plants, especially algae, differ in their absorption spectra, but unless sensors can be designed to fit each individual plant, there is no practical solution to this problem, and the alb provides no advance. If Einstein's first name be abbreviated to alb, let it be for an advance in science and not for a unit which solves no problems and adds to the confusion of light measurements.

SIR—To contradict Lewin's recent letter suggesting the alb as a radiation unit, instead of 'einstein', I consider that there is no confusion in the physics community about the use of the einstein. The ubiquitous ratio (velocity)/(velocity of light) = v/c is commonly known as β , and is otherwise not named. The authority for this statement is (1) your nearest friendly physics text, (2) excellent physicists, (3) one not-so-excellent physicist (L.X.F.).

Einstein's contributions to physics are incomparably wide and basic. So many units would be justifiably named after him than none is.

HANDBOOK OF HOLOCENE PALAEOECOLOGY AND PALAEOHYDROLOGY

edited by **B.E. Berglund**, *Department of Quaternary Geology,
Lund University, Sweden*

This handbook reviews the key palaeoecological methods applied to primarily organic lake and mire deposits. Particular attention is paid to Holocene environmental changes in the temperate zone, but most methods can be applied to older Quaternary deposits and to areas outside the temperate zone. The need for uniform methods of correlating stratigraphical data on a continental scale is emphasized.

THE CALEDONIDE OROGEN: Scandinavia and Related Areas

edited by **D.G. Gee**, *Sweden* and **B.A. Sturt**, *Geological Institute,
University of Bergen, Norway*

This book provides a complete coverage of the geology of the Caledonide Orogen in Scandinavia, set in the framework of the North Atlantic Caledonides. A large proportion of the volume concerns Scandinavia, describing the Orogen regionally, summarizing the Late Proterozoic and Early Palaeozoic history and treating a wide range of ongoing research. In addition overviews and in-depth discussions are provided on particular aspects of the Caledonide Orogen in other areas, such as Svalbard, North and East Greenland, the UK, the Northern Appalachians, France, USSR and Sardinia.

Healing in perversion

Michael Shepherd

The Breaking of Bodies and Minds: Torture, Psychiatric Abuse, and the Health Professions. Edited by Eric Stover and Elena O. Nightingale.
W.H. Freeman: 1985. Pp.319. Hbk \$21.95, £22; pbk \$11.95, £11.95.

TORTURE: "the art or process of inflicting severe pain, especially as a punishment, so as to extort confession, or in revenge". This is an impersonal dictionary definition of an unpleasantly personal topic, one which Voltaire saw as important enough to include in his *Philosophical Dictionary* of 1769 to underline its significance for the society of the day:

The Romans inflicted torture only on the slaves, but the slaves were not reckoned to be human. Nor does it appear that a judge . . . regards as a fellow man the haggard, pale, broken individual who is brought before him dull-eyed, with a long dirty beard, covered with the vermin that have been preying on him in the dungeon. He gives himself the pleasure of putting him to major and minor torture, in the presence of a surgeon who feels his pulse until he is in danger of death, after which they set to again. . . .

Until recently Voltaire's condemnatory views have been expressed by a relatively small minority, even though the twentieth century can claim some of the most savage examples of human barbarism in recorded history. On Human Rights Day in 1972, Amnesty International began its campaign against the systematic use of torture by governments, and in the following year published its disturbingly well-documented *Report on Torture* (Duckworth, 1973).

The *Report* included a full account of the medical and psychological aspects of torture and demonstrated by means of a survey that "torture has virtually become a world-wide phenomenon and that the torturing of citizens regardless of sex, age or the state of health in an effort to retain political power is a practice tolerated by others in an increasingly large number of countries". The topic has since attracted mounting attention and concern, though it was not until December 1984 that the Convention against Torture and Other Cruel, Inhuman or Degrading Treatment or Punishment was adopted by the United Nations General Assembly.

The psychological and psychiatric evidence, concluded the *Amnesty Report*, points to the existence of the potential to torture in *Homo sapiens*. Voltaire, who recognized torture as one aspect of the destructive element in man, would not have been surprised by these findings, while clinical observations have indicated that John Cowper Powys's admission that he could not remember a time "when sadistic thoughts and images did not disturb and intoxicate me" is unusual more by virtue of its frankness than by its con-

tent. Further, torture carries its own appeal. Writing of perhaps the most distressing scene in world literature, the blinding of Gloucester in Shakespeare's *King Lear*, Wilson Knight remarked shrewdly that, "The sight of physical torment to the uneducated brings laughter". And with the laughter goes a form of pleasure, widely exploited by pornographers and wholly unrelated to educational status.

The Breaking of Minds and Bodies, published under the auspices of the American Association for the Advancement of Science, should help carry the campaign against torture a stage further. Its subtitle, however, *Torture, Psychiatric Abuse, and the Health Professions*, is more informative than its title. The book is in two parts, one concentrating on general issues and the other on psychiatric practices in the Soviet Union, each containing five articles by various authors with several case-histories, along with editorial commentaries and three appendices providing codes of ethics, an inventory of relevant organizations and a selected bibliography. Much of this information is familiar and, indeed, three of the articles have appeared elsewhere. The principal purpose of the book, however, is not so much to record the activities of repressive governments as to explore how they have "enlisted the aid of medical practitioners in suppressing dissent and what steps need to be taken to prevent such professional complicity, and ultimately, to end the abuses themselves".

The message is all the more timely inasmuch as the involvement of the medical profession has not always been acknowledged. The medical profession, nominally devoted to the preservation of health and the saving of life, places great store on the ethical conduct of its members, as epitomized in the International Code of Medical Ethics, adopted by the World Assembly of the World Medical Association in 1949, which states categorically that "Under no circumstances is a doctor permitted to do anything that would weaken the physical or mental resistance of a human being except from strictly therapeutic or prophylactic indications, imposed in the name of his patient". In fact, as the evidence makes clear, medical practitioners continue to disobey this injunction, actively or passively, in many countries. Voltaire's pulse-taking physician, far from giving succour to the victims of torture, was participating in the process.

Why does this occur? The book focuses on psychiatrists in the Soviet Union, whose well-documented activities occupy a major part of the text. By employing their mental hospital system to coerce dissident but mentally healthy citizens and perverting clinical concepts for the purpose, the Russians have provided a new variation on an old theme. But anyone who has had contact with medical representatives of this system cannot fail to recognize, along with the cynical, unscrupulous apparatchik, the sincere, if misguided, believer in an ethical system codified in the Physician's Oath of the Soviet Union which, after mentioning the health of man and the care of disease, goes on to state: "I will in all of my actions be guided by the principles of communist morality, ever to bear in mind the high calling of the Soviet physician, and of my responsibility to the people and the Soviet state".

This chilling sentence draws attention sharply to the need for account to be taken of more than one set of ethical guidelines when assessing professional behaviour. As Heijder has pointed out (see *Professional Codes of Ethics Against Torture*, published by Amnesty International in 1976), such conduct is affected by at least four factors: political systems, public opinion, organizational units and individual codes of morality. The noxious doctor, like the immoral priest or the crooked lawyer or the dishonest scientist, is the product of all these forces, whose balance determines the answer to the question posed by a distinguished German-Jewish refugee who had left Germany early in 1933 after finding most of his colleagues at the university clinic dressed in Nazi uniform the day after Hitler's accession to power — in the event of such circumstances in this country, he would ask, how many of your colleagues would be wearing civilian clothes?

Clearly it is unnecessary to postulate a Joseph Mengele in the vast majority of those uniformed physicians. The central issue is how far association with or acceptance of any system which employs or condones torture in any form is compatible with a medical ethos which must be preserved if the profession is to maintain its public status and its self-respect. Stanley Milgram's disturbing experiments on obedience and disobedience in response to authority reinforce the fragility of personal conscience in conflict with social pressures and reinforce the verdict of the *Amnesty Report*, namely that "The prevention of torture . . . lies not in medical research but in political and legal remedies". The value of this book resides in its contribution to the heightening of public awareness and the facilitation of official action. □

Michael Shepherd is Professor of Epidemiological Psychiatry at the Institute of Psychiatry, De Crespigny Park, Denmark Hill, London SE5 8AF, UK.

Between a good read and a good reed

John C. Marshall

Children's Reading Problems. By Peter Bryant and Lynette Bradley. Basil Blackwell: 1985. Pp.116. Hbk £16.50, \$24.95; pbk £5.95, \$9.95.

Reading Ability. By Charles A. Perfetti. Oxford University Press: 1985. Pp.282. £25, \$35.

IN 1945 Herbert Hoover declared that the liquidation of illiteracy was one of the five or six major tasks for the postwar world. It still is. Even in the industrialized world a small but distressing minority of children experience great difficulty in learning to read and never achieve the fluent command of visual language that is necessary to participate fully in a technological society; what can be done for the 'slow learner' or the 'dyslexic' child? Many students in tertiary education who have mastered the nuts and bolts of reading complain of slow reading speeds and poor comprehension; can these young adults learn to cope better with the demands that professional life places upon true literacy?

These two books reach a similar conclusion on one key issue: the invention of the alphabet was a good idea, and a firm grasp of the alphabetic principle that letters (or letter groups) map onto the constituent sounds of words is of crucial importance in learning to read. Beyond this, the books differ greatly in both style and content.

The primary virtue of Bryant and Bradley's monograph lies not so much in their conclusion *per se* (advocates of so-called 'phonic' instruction have been with us for a century or more), but rather in their evidence for that conclusion. First reported in this journal (*Nature*, 310, 419–421, 1983), Bradley and Bryant have provided the most compelling demonstration that awareness of the relationship between letters and sounds is *causally* implicated in the efficiency with which children learn to read.

Children's Reading Problems contains a vigorous, albeit good-natured, attack upon the methodological and interpretative inadequacies of much previous research; it defends, more cogently than any other work I know, the central importance of phonic skills. The book is written in lucid English, quite free of psychological jargon. Parents and teachers should find Bryant and Bradley's simple description of their training methods of considerable practical value. More generally, Bryant and Bradley provide an acute analysis of how to conduct serious educational research on which practical decision-making could be rationally based.

One aspect of their work is, however, controversial. They fail to acknowledge the full import of the fact that English (or

French) cannot be read or written solely on the basis of letter-sound correspondence rules. The child who writes, YOT, or PLAZE (for "yacht" and "plays") has mastered the skills that Bryant and Bradley stress; likewise, the child who reads SHOE as "show" or SWEAT as "sweet". But to attain mature literacy the child must eventually come to read and write orthographically and forgo reliance on phonic rules; a good read is not the same as a good reed. One alarming consequence of Bryant and Bradley's over-reliance on phonological awareness is their belief that reading backwardness must have a solitary cause — failure to acquire normally the regular mappings between letters and sounds.

This flies in the face of the extensive evidence, from single-case studies, that backward readers (or 'developmental dyslexics') constitute a very heterogeneous population with striking qualitative variation from child to child in the nature of their impaired and intact sub-skills. Bryant and Bradley are well aware of this literature (they quote a few pertinent examples), yet they dismiss its significance on the peculiar grounds that analogous qualitative variation can be found in younger children who read at age level. This seems such an obvious *non-sequitur* — why should the balance of skills required to read normally at one age be identical with that required for normal reading at a later age? — that one is deeply puzzled to see it put forward by *developmental* psychologists.

By contrast with the straight but narrow path chosen by Bryant and Bradley, Perfetti reviews a substantial chunk of the primary literature on all aspects of reading ability in both children and adults; the discussion ranges from word recognition to text comprehension, from the analysis of eye movements in skilled reading to the role of verbal short term memory, and from brain laterality to computerized reading instruction. Many of the studies

reported are as relevant to speech processing and oral comprehension as they are to reading and writing. These review chapters are solid and workmanlike, although somewhat heavy going; Perfetti's turgid style lacks the sparkle and excitement of Bryant and Bradley's clear arguments.

Perfetti's own "verbal efficiency theory" succeeds in showing that comprehension of a written text is a complicated business but provides little real insight into the mysterious processes of "propositional assembly" and "propositional integration". Much of this research has a curiously circular flavour. Groups of high- and low-ability readers are selected and then shown to differ on a variety of reading-related skills. The unproductiveness of such a strategy derives in part from the use of heterogeneous groups; it is thus unclear whether a particular impairment is characteristic of all low-ability readers or solely that of a subgroup. Many of the studies also fail to distinguish between cause and effect; an impairment of "verbal intelligence" could be a cause of poor comprehension, but equally the failure to learn from reading may be reflected in poor performance on other language tasks. In contrast, Bryant and Bradley's discussion of how to disentangle cause and effect is particularly incisive.

These problems assume major significance in Perfetti's chapter on dyslexia. He tentatively concludes that "dyslexia may be the low end of an ability continuum rather than a qualitatively different problem." But once again, the failure to distinguish individuals from groups renders the conclusion suspect. Indeed, the very concept of a single ability continuum seems misguided when we are dealing with cognitive functions, such as reading and writing, whose effective deployment depends upon a large range of subcomponents. □

Some mistake? Thomas Bennett's "Eureka" driving wheel for bicycles of 1897, which, he boasted, made "practically a frictionless machine". The illustration is reproduced from *A Victorian World of Science*, by Alan Sutton, published by Adam Hilger price £12.50, \$20.

Into the generation of application

Karol Sikora

Hybridoma Technology in the Biosciences and Medicine. Edited by Timothy A. Springer. *Plenum: 1985. Pp.602. \$75, £71.*
Human Hybridomas and Monoclonal Antibodies. Edited by E.G. Engelman, S.K. Foug, J. Larrick and A. Raubitschek. *Plenum: 1985. Pp.526. \$69.50, £66.*

SINCE the discovery, ten years ago of monoclonal antibodies, several books about these biologically useful tools have been produced. Until now, however, they have tended to concentrate heavily on methodology. But we are beginning to see the emergence of second generation volumes which provide the reader with much more sophisticated detail on the application of the technology. These two books are in this category.

The first, edited by Timothy Springer from Harvard University, starts with a rather dry title. However, in it the editor has managed to get together a group of authors who take us through some of the more elegant approaches to the construction and characterization of monoclonal antibodies. Recent developments in hybridoma technology involved in the production of monoclonal antibodies — peptide immunization, the expression of cloned immunoglobulin genes, and exon shuffling and class switching — are all considered and fully referenced. I know of no other source to date where this information can be found in one place. The merger of gene cloning and the monoclonal antibody fields promises to bring mutual benefit. Designer monoclonal antibodies — that is those produced with the required secondary functions by recombinant gene technology, may now become a reality, whilst the speed of cloning defined genes can be aided by having an appropriate antibody to the resulting protein.

The second section consists of a series of reviews on the biomedical application of monoclonal antibodies. Some of these are rather unoriginal and now dated, especially those concerning clinical applications. The final section considers T-lymphocyte clones and their products. Unfortunately this field has moved too fast for the publisher and although there are some useful background reviews little recent information is to be found. Altogether this is an interesting volume, containing much useful reference material about new ways to produce and improve monoclonal antibodies, but it could easily have been shortened without detriment by removing some of the reviews on specific applications.

The production of human monoclonal antibodies has captured the imagination of many over the past five years. Their

advantages in allowing a direct examination of the human immune system and the potential lack of immune response to them on injection suggest that they will be more useful clinically than their rodent counterparts. But there are tremendous technical difficulties in their production and these problems are addressed by the contributors to the first volume specifically to be concerned with human monoclonal antibodies.

The technical problems and how they can be overcome are considered in the first part of the book, which provides recipes for mouse-human and human-human hybridization as well as the use of Epstein-Barr virus to achieve immortalization. The production of human antibodies to cancer cells, infectious agents and self antigens in autoimmune disorders such as diabetes and systemic lupus erythematosus are reviewed. An interesting mixture of chapters then considers specific aspects such as the study of human-human hybridomas in immunodeficiency, the use of electrofusion techniques and the generation of human

T-lymphocyte hybridomas. There follows an appendix listing methods for tissue culture and assaying supernatants and recipes for media. Lists such as these have little to do with human monoclonal antibody production specifically and are readily available elsewhere; so, again, the book is unnecessarily long despite having a useful summary of current work in this difficult area. The considerable interest of the biotechnology industry here, together with recent developments in handling and expressing human genes, will almost certainly ensure rapid development of this field.

Now that monoclonal antibodies are impinging on wide areas of biological and clinical science there is a great need for books to function as knowledge conversion kits similar to those available for upgrading construction toys for children. This would save readers considerable time and money. □

Journey to adulthood

Leonard A. Freed

The Growth and Development of Birds. By Raymond J. O'Connor. *Wiley: 1984. Pp.315. £22, \$34.15.*

BIRDS are extremely varied with respect to the size and composition of their eggs, the nature of the nests they provide for eggs and neonates, and growth and development both during incubation and after hatching. They range from species without parental care following egg-laying to those in which care continues to long past the fledging stage.

Growth and development occur in: (i) a thermal environment influenced by nest, parental brooding, brood size, and maturation of individual endothermy; (ii) a nutritional environment influenced by diet and frequency of feedings; (iii) a social environment in which there is parent-offspring interaction, sibling rivalry for parental attention, and interaction with conspecifics during dispersal, migration and recruitment for breeding; and (iv) a demographic environment with risks of mortality at each life-history stage. The nature and combinations of these environments differ between taxonomic groups (indicating phylogenetic constraints on developmental patterns), as well as within them for species in different ecological circumstances (indicating evolutionary adaptation of developmental patterns).

Raymond O'Connor's *The Growth and Development of Birds* is an important first review of aspects of these environments through its attempt to combine physiological, behavioural and ecological studies

within an evolutionary perspective. The book is structured around the avian life-cycle, bringing together discussion of an unusually wide range of topics — including those mentioned above — and comparing altricial and precocial species for many of them. The goal of the book is clearly breadth rather than depth of coverage. But while specialists may be disappointed by the absence of certain details to do with their particular research interest, or the scarcity of work published after 1980, they will undoubtedly be stimulated by seeing their area put in context and perhaps moved to examine aspects of it they might previously have overlooked.

Readers should be aware that several topics (for example asynchronous hatching and optimization of growth rates) have become increasingly controversial since the book was written, and also that most examples are based on North Temperate species. Tropical birds, with different life histories and social structures, remain understudied in all aspects of growth and development. Nevertheless, the book will be read with profit by a wide range of biologists, and beginning graduate students and undergraduates will here encounter features of growth and development that they would be unlikely to come across in any single course. □

• Academic Press has just published the third volume in the series *Form and Function in Birds* edited by A.S. King and J. McLelland, the emphasis in this volume is upon locomotion and the special sense organs. Price is \$99.50, £90

Out of space, out of time

John D. Barrow

Relativistic Astrophysics. By M. Demiański. Translated by A. Pol. Pergamon: 1985. Pp.341. £25, \$45.

RELATIVISTIC astrophysics means different things to different people. To some it is special relativistic astrophysics with an emphasis upon the physical complexities of high-energy radiation processes, pulsars, accretion disks and neutron stars; to others it means general relativistic astrophysics and the exotic realm of ultra-strong gravitational fields; black holes, gravitational collapse and gravitational waves. Marck Demiański's text is of the general relativistic sort.

The author assumes the student possesses a basic knowledge of general relativity and tensor calculus, the basics of which are completed by page four. The book then commences proper with a succinctly written study of black holes, including a real derivation of the Kerr solution via the Ernst potential and a study of its orbits; derivations of the laws of black hole mechanics and thermodynamics together with simple analyses of the stability of the Kerr and Schwarzschild black hole solutions come later.

Between these discussions of areas which have been of special interest to the author is sandwiched a less compelling section of relativistic hydro- and thermodynamics, with a heavy emphasis on for-

malism that in subsequently put to little use. But good chapters follow on the stability of isolated self-gravitating bodies in Newtonian and general relativistic gravity with a detailed discussion of the effects of rotation. There are less quantitative surveys of astrophysical processes in the vicinity of black holes and neutron stars but these fall short of the standards set by other recently published textbooks — in particular that of Shapiro and Teukolsky's *Black Holes, White Dwarfs and Neutron Stars* (Wiley: 1983).

The final chapter, devoted to cosmology, is very disappointing. Here, the fact that the text was first written in 1978 finally catches up with the publishers. Although the earlier chapters on mathematical aspects of relativistic astrophysics have not dated during the prolonged translation period, the subject of cosmology has been revolutionized to such an extent that the author's discussion of physical processes in the early universe and galaxy formation is seriously out of date. The most recent references in the bibliographies are to works published in 1978 and 1979.

As the starting point for a second course on general relativity and its non-cosmological applications this book can be recommended to students for its systematic and lucid exposition, but the reader who is interested in contemporary ideas in astrophysics and cosmology will find that the story told by Demiański has been rather overtaken by Old Father Time. □

Going through the changes

Rita Cruise O'Brien

Stacking the Chips: Information Technology and the Distribution of Income. By J. Bessant and S. Cole. Frances Pinter, London/Rowman & Allanheld, 81 Adams Drive, Totowa, New Jersey: 1985. Pp.290. £17.50, \$26.95.

GETTING beyond the generalities and hyperbole in discussion of the effect of information technology on developing countries has been an uphill struggle. At a recent meeting of the North-South Roundtable (Society for International Development) on this topic, which included leading government spokesmen, scholars and business people, it became clear that some progress had been made. For some years the approach "Information Technology: Blessing or Plague of the Third World" prevailed making it difficult at times to make a sensible contribution.

Central to researching or writing about

informatics and development are questions of opportunity cost, technology transfer, income distribution and employment effects. I prefer to consider small corners within the field such as the experience of a single country or a particular problem which might be illustrative of others. For example, was it a wise government directive to have automated the Brazilian banking system, making banks more efficient at international dealing and trading, while destroying many jobs at the clerical level inside the country's banks? The authors of *Stacking the Chips* however, have opted for comprehensive analysis and refinement of economic modelling on the subject.

The authors did their work at the Sussex University Science Policy Research Unit (a centre of excellent research both on industrialized and developing countries) on a grant from the UN Institute for Training and Research. Ostensibly the book is about the effects of high technology on the distribution of income. The authors obviously felt it necessary to clear a lot of the ground first but instead of then delving more deeply into the subject, they introduce many different variables covering a

wide range of sectors. The analysis therefore in either scholarly or policy terms is rather unsatisfactory.

They provide a good introduction to the macro-economic literature on informatics and industrialization, employment and the comparative advantages, for example. But it ought to have been set out in a clearer more coherent manner. It is, for example, impossible to make quick reference to tables, which are not well labelled. The authors use a curious character coding which is difficult to follow because the key is to be found on Table 6.2, which is mentioned without giving a page reference. Books ought by first principles to be easily read and understood. And for students, hungry for material on the subject, the splendidly researched literature review is a hesitant and much qualified academic discussion rather than a clear indication of controversy or major contributions to knowledge.

Stacking the Chips works on a model developed by Cole in 1982 which demonstrated that technological change produced significant employment and distributional effects. This book, by its own description, attempts a very crude interpolation of available research evidence, despite Raphael Kaplinsky's warning in *Microelectronics and Employment Revisited* (ILO, Geneva, 1985) about the major gaps in coverage, methodology and analysis. After reading this latest contribution, I conclude that much indeed still needs to be done.

The conclusion that new technology does not necessarily lead to job destruction in the long term, but that shorter term structural problems are evident, repeats old caveats, many of which were pioneered at the Sussex University Science Policy Research Unit. With the exceptionally broad brief chosen by the authors, the obvious can only be reaffirmed. If in future they are at all interested in studies dealing with fewer technologies, sectors and a more modest terrain than the global economy in eight segments, I look forward to the sequel. □

Small-scale processes in the upper ocean boundary layer

S. A. Thorpe

Institute of Oceanographic Sciences, Brook Road, Godalming, Surrey GU8 5UB, UK

Here I review some of the recent advances in our knowledge of the physics of the upper ocean boundary layer at scales of micrometres to tens of metres, with emphasis on the nature of turbulence in the layer. A study of sub-surface bubbles produced by breaking wind waves offers some hope of revealing more of the turbulent processes, and indicates that bubbles may be important in the transfer of gases from air to sea.

OCEANOGRAPHERS are presently paying increased attention to the small-scale processes which operate at, or near, the sea surface. With rare exceptions, interest has been dormant since the exciting era in the 1950s when people such as Woodcock¹ were actively involved in seeking solutions to questions of air-sea interaction which required information about the small-scale physics, notably those relating to the production of spray and aerosols. As often happens, it has partly been the development of novel instruments which has revived this area of interest. The use of microwave satellite sensors—the synthetic aperture radar and scatterometer—and surface X-band radar has prompted new questions about the small-scale topography of the sea surface to which the instruments are sensitive. These questions must be answered if we are to make effective use of the measured data, perhaps to infer wind stress from the scatterometer by relations which are better than empirical, and hence improve the representation of atmospheric forcing in global models of ocean circulation. Better estimates of air-sea gas fluxes are required for global budget models and, for example, to enable oceanographers to use tracers such as tritium (with helium decay) to date water masses which lose contact with the surface and pass into—and ‘ventilate’—the main thermocline.

Some of the answers are already becoming available (in particular, studies² have been made of microwave scattering from breaking waves). Even the perennial questions of the role and importance of breaking waves in the transport of momentum from air to sea and of their generation of turbulence in the sea itself are close to being answered in a quantified way^{3,4}, although we still require a clear explanation of some puzzling but well-known phenomena, for example why it is that whitecapping is less frequent when it is raining than when it is not, other factors (for example, wind speed) remaining the same.

The fundamental question which remains to be answered is ‘What is the nature of turbulence below the sea surface?’ This

question concerns the ‘mixed layer’ or, to avoid ambiguity, the ‘upper ocean boundary layer’ (either term may include the seasonal thermocline). Some of the mechanisms affecting the turbulence are illustrated in Fig. 1. Moisture flux and radiative effects, essential in studies of convection, will be mentioned only in passing. I have also not discussed fronts; they are usually larger than the scales that I have chosen to describe.

Ocean/atmosphere similarities

It has frequently been assumed that the dynamics of the upper ocean boundary layer are similar to those of the atmospheric boundary layer. Indeed, studies of both mean quantities and fluctuations provide evidence in support of this hypothesis, although without exception the volume of data which is available for comparison is sparse and scarcely sufficient to confidently establish a similarity.

The mean flow in the upper few metres of the ocean and lakes has been measured by Churchill and Csanady⁵ in neutral conditions (those in which atmospheric heating or cooling is negligible). The near-logarithmic variation of speed with depth found by observing the motion of floats is similar to that of the wind in the atmosphere. Two of the authors’ conclusions are particularly remarkable. The ‘roughness length’ in the water (a length scale found empirically from the observations and, as the name implies, some measure of the nature of the surface) is some two orders of magnitude greater than that in the air (of the order of tens of centimetres rather than a few millimetres). Second, in conditions when the wave field was strongly affected by swell, much higher values of friction velocity, u_* (equal to the square root of the stress divided by the fluid density), in the water were inferred than could be explained by a conventional wind-drag relationship. The authors suggested, however, that this might be accounted for by the greater importance in these conditions of the wave-induced mean drift in the water—the

Fig. 1 Some of the mechanisms affecting turbulence in the upper ocean boundary layer. The spiral-like structure of the mean current (U) is due to the Earth’s rotation and reverses in sense in the Southern Hemisphere. The orientation of the ‘billows’ labelled ‘shear-induced turbulence’ is determined by the mean shear, so that their (horizontal) axes are not at right angles to the wind (that is, on average, angle $\alpha > 0$ in the Northern Hemisphere). Breaking surface waves and Langmuir circulation are, in particular, processes responsible for redistributing floating particles or biota. Breaking internal waves are included in the diagram, although they are not discussed in the text; they may be important in affecting the flux of nutrients and occasionally have an effect at the sea surface itself (see ref. 41). The wakes of ships will rarely be significant contributors to the net fluxes, except with respect to low-frequency sound!

Fig. 2 Temperature fluctuations measured at the indicated depths from a spar hanging beneath a towed catamaran near 38°40'N, 12°50'W in October 1984 in daytime under clear skies. The wind speed was $\sim 7 \text{ m s}^{-1}$. Time variations have been converted to distance using the mean towing speed through the water, 1.9 m s^{-1} . Some of the abrupt temperature rises are marked by arrows.

'Stokes drift'. (The use of floats, or 'drifters', to measure drift currents may, however, be less than ideal because of the higher than average horizontal currents found below wind rows towards which floating objects tend to be drawn; I shall address Langmuir circulation below.) Flows in non-neutral conditions have yet to be closely studied in the ocean. However, it is known that the diurnal heating cycle can have a profound effect in modulating the oceanic near-surface stratification and currents, just as it does in the atmosphere⁶. A diurnal modulation of the current in the near-surface ocean, a variation resembling the well-known nocturnal jet in the atmosphere⁷ but being essentially a daytime event, has been observed⁸ and modelled^{8,9}; it results from the daily cycling of the layer depth into which wind-driven momentum is distributed as the stratification varies due to solar heating, and the subsequent inertial development of the current under the effect of the Earth's rotation.

Turbulence in the atmosphere is driven by convection and by the stress of the wind on the underlying boundary. In the ocean, turbulence may be similarly driven by convection and by wind stress, although less directly as waves act as an intermediary (see below). In the case of turbulent motions in near-neutral conditions, a similarity of the horizontal velocity spectra in lakes and ocean has been found¹⁰ when they are scaled with depth, z , and friction velocity. The spectra collapse into the canonical spectral form of flow in a turbulent boundary layer, as determined by laboratory experiments (ref. 11; see also ref. 12). The scaling of the rate of dissipation of turbulent kinetic energy in the ocean, ϵ , with the cube of the wind speed¹³ and inversely¹⁴ with depth provides more support for constant stress layer similarity, but these are relationships which deserve further investigation. Such investigation is now possible through the development (notably by Dillon; private communication) of upward-profiling turbulence probes capable of measurements right up to the sea surface. The most convincing demonstration of similarity between the oceanic and atmospheric boundary layers is perhaps the study of convective conditions in the ocean¹⁵ and the comparison with atmospheric data¹⁶. It is found that in both the ocean and the atmosphere, ϵ is uniform throughout much of the layer where convection dominates over the effects of surface stress (that is, beyond a Monin-Obukov length from the surface) and is proportional to the effective flux of buoyancy due to the heat passing through the surface. It is only near the surface that differences between the atmosphere and ocean appear significant (that is, $z/D < 0.3$ in the comparison of ref. 15, where D is the depth to which convection extends, here $\sim 150 \text{ m}$). The turbulence probes used in that study are now being used to address fundamental questions about the turbulent structure of stratified fluids and to obtain the measurements of turbulence and diffusion in the upper ocean that are

required for numerical models of the ocean (see, for example, ref. 17).

One other measurement in which similarity is found between ocean and atmosphere is that of temperature structure. Temperatures measured at fixed positions in the atmospheric boundary layer are found to have a 'sawtooth' pattern, with rather abrupt changes (predominantly in the same sense in given conditions of heat flux) being followed by relatively gradual ramps, thus leading to skewed temperature derivatives¹⁸. Similar skewed gradients have been reported from towed or moored instruments in a lake¹⁹, and have now been observed at sea (Figs 2, 3). In conditions in which the heat flux leads to stable stratification, the skewness measured in upwind tows (or from moorings) is positive; it reverses sign in downwind tows. Intriguingly, the skewness usually appears to be slightly positive in tows made to the right of the wind ($\theta = 90^\circ$ in Fig. 3; this is reversed in tows to the left of the wind), presumably because the Ekman flow, the rotation of the current vector with depth due to Coriolis forces, leads to a pattern of eddies or 'billows' which are, on average, rotated as sketched in Fig. 1 (the features labelled 'shear-induced turbulence'). If so, the trend should reverse in the Southern Hemisphere. It has not yet been established that inverse temperature ramps and skewness of the opposite sign are found in convectively unstable conditions in the ocean, but this may be expected from experiments in the laboratory and in the atmospheric boundary layer²⁰. Specifically, the sign of the skewness of the streamwise temperature gradient, sign S , is given by sign $(\mathbf{x} \cdot \Delta T \times \boldsymbol{\omega})$, where \mathbf{x} is a vector in the flow direction, ΔT is the gradient of the mean temperature and $\boldsymbol{\omega}$ is the vorticity of the mean flow.

The existence of temperature ramps—and these have some coherence in the vertical (see Fig. 2)—suggests the presence of organized structures²¹; this is not surprising as large coherent structures are now known to be a feature of turbulent shear flows. We need, however, to discover whether significant vertical fluxes of heat and momentum are carried by these structures in the ocean for, if this is the case, it might be possible to devise a semi-deterministic model of the turbulence by specifically accounting for their presence. The construction of such a model is feasible, especially if, as is possible, the flow is close to marginal stability in conditions of stable heating^{22,23} and the ramps are related to the most 'dangerous', or—once instability occurs—most rapidly growing modes.

Langmuir circulation

This brings me to comment briefly, but emphatically, on the near-surface organized structure consisting of alternating vortices aligned downwind which are known as the Langmuir circulation. This is well known to produce a coherent structure

Fig. 3 Variation of the skewness of the temperature derivative, S , measured in tows at constant depth at different angles, θ , to the wind when the net air-water heat flux is positive. The circles represent measurements made at sea (for example, in the Northern Hemisphere, as in Fig. 2) and the squares represent measurements from Loch Ness¹⁹. Corresponding values of S at $\theta=0$ in the atmospheric boundary layer are in the range 0.4–0.85 (refs 18, 20).

at the sea surface—the associated wind rows into which floating material is carried—and, as Leibovich²⁴ has suggested, we might also account for its effects on the fluxes below the surface in a deterministic way.

It is a profound embarrassment to physical oceanographers that we have not yet established whether, or when, Langmuir circulation is important in distributing heat and momentum in the upper ocean or in forming the seasonal thermocline. This has remained one of the most challenging but well-defined tasks in physical oceanography since Langmuir wrote his definitive paper 47 yrs ago⁴². Recent observations made from the ocean research platform Flip²⁵ have demonstrated that, in addition to the enhanced downwind velocities which I mentioned above, remarkably large downward velocities can be measured beneath wind rows. The vertical momentum carried by these circulations—the associated Reynolds stress—appears too great in some of the cases studied to be in equilibrium with the local wind, suggesting a considerable variability in structure; more observations are required to link measurement to theory. Whether the circulation has an immediate counterpart in the atmospheric boundary layer depends on how it is generated or on which theory one accepts. The most plausible theory (in that it best satisfies the existing observations) is that development by Craik and Leibovich²⁴. The pattern of streamwise vortices is generated by the interaction of waves and mean shear. Some of the theoretical predictions have been verified in the laboratory²⁶. We know the mechanism works, but is it the source of circulation in the ocean, and can theory be used to predict the associated fluxes?

Breaking waves

The differences between oceanic and atmospheric boundary layer dynamics are due partly to radiative and evaporative processes, but also to the asymmetrical nature of the sea surface, the turbulence generated by breaking waves, and the relative importance of mean flow, wave-induced motions and turbulent fluctuations. A fundamental asymmetry is found in the shape of surface waves; they have narrow crests and relatively broad troughs. The formidable nonlinearity of the boundary condition at the free surface makes the theoretical study of wave instability and of the onset of breaking one of great complexity, yet considerable advances have been made (see, for example, ref. 27). It has long been known that breaking occurs at or near the wave crests; this results in the production of sub-surface bubbles and of foam sometimes compacted into a layer many bubbles deep. Spray, the antithesis of bubbles, is thrown into the air, but whilst the opposite of foam—drops of water surrounded by air but resting on the interface—does occur briefly, the drops are very unstable and do not build up into compact layers. It is almost frivolous to mention that rarely is there in the ocean a deep source of rising bubbles; the antithesis of rain is rare. One

particular feature pertinent to the role of bubbles in contributing to the gas flux across the sea surface is that they have only to be carried down to a depth of ~ 10 m before their internal pressure is doubled hydrostatically. Spray, on the other hand, has to ascend to over 5 km before it experiences a reduction in pressure to a half of that at its origin at the sea surface. The wind speed at 10 m above the sea surface, W , is usually comparable to the dominant wave speed, c . The turbulent and wave-induced fluctuations in the air are comparable in magnitude, but are generally less than the wind speed. In the near-surface ocean, however, the wave speed and the wave particle velocities usually greatly exceed the mean flow and the turbulent fluctuations. Motion is dominated by waves. The critical layer where the wave speed matches the mean flow occurs in the air rather than in the water. (The water, however, generally carries the greater momentum per unit volume, and has a much greater heat capacity.)

The development of multiply connected surfaces as waves overturn and fluid re-enters through the water surface, allows the waves to generate vorticity (a characteristic of turbulent motion) even in a pre-existing irrotational flow; the conditions (described by Kelvin's circulation theorem) in which vorticity is conserved are violated. There are several possible candidates responsible for producing turbulence in breaking waves, perhaps the most obvious of which is instability at the head of, and around, the injection jet at the tip of a plunging wave after its entry into the water surface. A second candidate is the wake region of large rising bubbles, especially spherical-cap bubbles, entrained by a breaking wave. But a more potent and frequent source in both plunging and spilling breakers appears to be the shear layer formed between the spilling water of the breaker zone moving at about the speed of the wave crest and the underlying water moving backwards relative to the crest. The instability of this shear zone may be the source of oscillations in the spilling zone of breaking waves observed by Banner and Fooks².

Very little is known of the nature (for example, spectra and patchiness) of wave-induced turbulence, although this is becoming an active area of research. Some recent advances, especially those in laboratory experiments, are reviewed in the proceedings of a conference held recently in Japan²⁸. Most of the measurements of velocity fluctuations very near the sea surface have been concerned primarily with those at, or near, the wave frequencies. Early measurements at higher frequencies²⁹ concluded that almost all the turbulent energy produced by waves must be dissipated in the upper few metres, whilst Russian workers³⁰ found that the near-surface Reynolds stress decreased with depth and appeared to be associated with wave frequencies. Kitaigorodskii *et al.*³¹ have recently analysed measurements of turbulence made with a drag sphere mounted on a lake tower, and conclude that there is intense wave-generated turbulence

in the region immediately below the surface, of thickness about 10 times the mean wave amplitude, ζ , whilst at greater depths the turbulence has the character of the conventional constant stress layer. The region of wave-generated turbulence is quite thick: values of ζ of 2 m, which is not uncommon, imply that the region extends to 20 m below the surface! Further work is required to substantiate these observations.

Bubbles and turbulence

Clouds of sub-surface bubbles produced by breaking wind waves can be detected by narrow-beam upward-pointing sonars moored or mounted on the sea bed^{32,33}. The mean depth to which these clouds of bubbles extend, \bar{d} , non-dimensionalized with wavelength, λ , increases with the ratio of wind to wave speed, W/c ; typically, in open sea conditions, \bar{d} reaches 10 m for winds of $\sim 14 \text{ m s}^{-1}$. The acoustic scattering cross-section of the bubble clouds at a fixed depth, M_v , a measure of the approximate area of the bubbles per unit volume when the sonar frequency is sufficiently high, increases rapidly with wind speed (roughly as W^{12}) but decreases roughly exponentially with depth with a decay scale of 0.5–2 m. In high winds the status layer of bubbles formed below the surface can be dense enough to muffle the ambient noise in the sea produced by breaking waves³⁴.

The challenge is to solve the inverse problem—to obtain information about the turbulence from the measured vertical distribution of the bubble clouds; this has been attempted by comparing the observed distribution with predictions from models based on a balance between turbulent diffusion, the upward buoyant rise of bubbles of a given radius, and the flux in radius space due to bubbles being compressed hydrostatically as they are carried downwards or by their exchanging their constituent gasses with those dissolved in the water. Several assumptions made in the models raise further interesting questions about the turbulent dynamics near the sea surface and the analogies between water droplets in the atmosphere and bubbles in the sea. Various representations of turbulence have been tried³⁵, the most successful being that of adopting an eddy diffusion coefficient, K_v , of the classical boundary layer form, ku_*z , where k is Von Karman's constant. The values of u_* required for agreement with the observations are, however, greater than those derived from the wind speed, assuming a typical drag coefficient and continuity of stress across the sea surface. The ratio is close to unity for W/c near 2, but increases to ~ 2.5 for $W/c = 0.8$, when swell is of greater importance in the wave field. This result, reminiscent of Churchill and Csanady's⁵ conclusions based on drift currents, deserves further critical and careful investigation. A fit using a form of K_v which tends to a constant value in the surface layer but tends to the conventional ku_*z at depth, and which assumes that u_* is given by the wind drag, gives a mean surface layer thickness of 9.7 ζ ,

which is intriguingly close to the conclusion of Kitaigorodskii *et al.*³¹ concerning the region dominated by wave turbulence.

The temporal variation of bubble clouds at a fixed position (and this is what is measured by a moored sonar) can be linked via advection and the lifetime of bubble clouds to the spatial and temporal distribution of the breaking waves which create them, and so to the whitecap area. Here there is the prospect of linking bubbles, turbulence, waves and foam to the questions of momentum transfer³⁶. We are again moving towards more deterministic models of forcing the turbulence in the sea; momentum is injected in pulses when wave groups break at a rate just in balance with the wind-forced growth of waves between breaking events^{3,4}.

Gas transfer

I must finally mention gas transfer because this is another area of upper ocean research in which significant advances are being made. Kitaigorodskii³⁷ has directed attention to the importance of patches of enhanced turbulence generated by breaking waves in changing the thickness of the viscous sublayer at the surface across which gases are exchanged with the atmosphere. Others^{33,38,39} have pointed to the possible importance of bubbles. As bubbles are carried beneath the surface, their internal pressure increases considerably and this acts like a piston to drive gas into the surrounding water, at least until the water itself becomes supersaturated. The equilibrium condition is thus one in which the water is supersaturated, with a balance being achieved between the input of gases via the bubbles and the evasion of gas through the sea surface. (Here is another feature of the asymmetry of the air-sea interface.) The bubble production increases with wind speed and so does the level of supersaturation at which equilibrium occurs. Present measurements suggest that in typical wave conditions, a mean wind speed of $\sim 8 \text{ m s}^{-1}$ may be sufficient to support a 3% supersaturation level in the water, about the average reported for oxygen in the Pacific⁴⁰. However, as M_v (and hence bubble area) increases rapidly with wind speed, an occasional storm may be sufficient to maintain enhanced levels of supersaturation equivalent to those produced by other processes (for example, biological).

Conclusion

We are slowly approaching improved, better determined and less empirical models of the upper ocean boundary layer through attention to small-scale processes. To be properly interpreted, these processes demand an understanding of the physics from scales upwards of a few micrometres, the size of the smallest bubbles. The processes are essential elements in the exchanges between the atmosphere and the ocean, and advances in understanding them will lead to improved estimates of the global budgets of energy, heat and gases.

Mr Alan Hall provided the data shown in Fig. 2.

Solar signature in sedimentary cycles from the late Precambrian Elatina Formation, Australia

G. E. Williams* & C. P. Sonett

Department of Planetary Sciences, Lunar and Planetary Laboratory, University of Arizona, Tucson, Arizona 85721, USA

Climatic cyclicity is recorded by regular variations in the thickness of varves in the Elatina Formation, a late Precambrian periglacial lake deposit in South Australia. Earlier conclusions that the climatic cycles reflect solar variability are strongly supported by a complexity of periods revealed through study of drill cores of the varved sequence. The new data promise to contribute significantly to our understanding of solar processes.

APPARENT solar periods (principally ~11 and ~22 yr) were previously recognized^{1,2} in thickness variations of varved (annually layered) periglacial lake deposits of the late Precambrian Elatina Formation in the Flinders Ranges, South Australia. Because the rocks are not well exposed, diamond drilling was carried out in December 1982 to obtain a complete cored sequence of the ~10-m-thick varved interval. Some drill core was lost through rock fracturing, so a group of three vertical holes was drilled to allow matching of cores and construction of the longest possible continuous varved sequence. Logging the drill cores and correlation of the three sequences³ produced a stratigraphically continuous log, 9.39 m long and spanning an estimated ~19,000 yr VT (varve time), which could be measured precisely.

The new data reviewed here support the original conclusion that solar periods are recorded by the rocks, and may prove invaluable to our understanding of the solar activity cycle.

Geological setting

The Elatina Formation at Pichi Richi Pass in the Flinders Ranges, South Australia, comprises siltstones and fine sandstones deposited in a periglacial lake during the Marinoan Glaciation ~680 Myr ago¹⁻⁴. The occurrence of sand wedge structures in a penecontemporaneous fossil permafrost horizon within the adjacent palaeo-catchment area provides good evidence of a markedly seasonal, arid Marinoan periglacial climate⁴ and implies strong seasonal control on meltwater discharge into the periglacial lake.

The laminated interval of the Elatina Formation records climatic cyclicity through regular variations in the thickness and grain size of graded (fining-upward) laminae up to 3 mm thick (Fig. 1) that were deposited by density underflows in the distal portion of the lake^{1,2}. Scattered 'drop grains' up to the size of small pebbles were probably derived from melting river ice. The interval is characterized by conspicuous groups or cycles of about 10-14 laminae that are usually bounded by thinner, darker, more clayey laminae. The thickness of laminae varies systematically within each cycle, attaining a maximum near the cycle centre. A cycle 'doublet' of alternate thick and thin cycles is common (Fig. 1) and longer rhythms are evident through regular changes in cycle thickness.

The non-random variation in thickness of the graded laminae, together with the envisaged palaeogeographical setting and strongly seasonal arid palaeoclimate, provide good evidence that the laminae record non-random spring or summer meltwater discharge into the lake and that each lamina is, therefore, an annual increment or varve. The laminae are similar to the 'intermediate distal facies' in the varve classification of Smith⁵, which comprises delicate but distinct varves with summer layers usually too thin to display sublaminae. Through comparison with modern glaciolacustrine sedimentation⁶, varve thickness is interpreted as a measure of relative mean annual temperature. Plots

Fig. 1 Cyclic lamination in drill core from the Elatina Formation, Pichi Richi Pass. Conspicuous cycles comprise groups of ~10-14 graded laminae of silt to very fine sand grade, bounded by thinner, darker, more clayey laminae. The lower half of *b* displays cycle 'doublets' resulting from alternate thick and thin successive cycles. Scale bar, 1 cm.

of varve and varve-cycle thickness against time^{1,2} therefore may also be viewed as plots of time-variation in relative mean annual temperature. As the thinnest varves reflect the coldest portion of the climatic spectrum, their more clayey composition may be attributed to deposition of suspended fines through more widespread freezing or major overturn of cold surface waters¹. The scattered distribution of 'drop grains' throughout the cycles, with no preferred concentration in particular laminae, suggests, nonetheless, that significant pauses in annual density underflow events did not occur near varve-thickness minima.

Time-series analysis

From thickness measurements of drill-core material, distinct periodicities have been identified in two related sequences: (1) a detailed sequence of 1,337 varves obtained from enlarged photographs of thin-sections; (2) a long sequence of 1,580 cycles, each cycle comprising from 8 to 16 varves, obtained from the composite log of the drill cores.

Thicknesses were determined with a precision of 0.01 mm at the Laboratory of Tree-Ring Research and recorded on a floppy disk; the data were then transferred to the Lunar and Planetary Laboratory's INTERDATA 8/32 computer for time-series analysis.

Detailed sequence. Well-preserved varves contained in a piece of core 93 cm long were measured from photographic enlargements (4.4×) of overlapping thin sections³. In places very thin varves, possible random (intra-annual) layers¹, and rare soft-sediment deformation made counting uncertain. Such places were few, however, and indicate an accuracy of ±5% for the count of 1,337 measurements.

The 1,337 varves span 110 complete cycles near the top of the core sequence of 1,580 cycles (cycles 1,405–1,514). Conspicuous fluctuations in varve thickness (Fig. 2) define a cycle ranging from 8 to 16 yr VT in duration and with a mean period of 12.0 yr VT (Table 1a). The cycles show an overall tendency to positive skewness, the mean ascent period being 5.57 yr VT and the mean descent period 6.45 yr VT. Characteristically, varve thicknesses fall to approximately the same minimum level every ~12 yr VT (mean = 0.19 mm, s.d. = 0.07 mm), whereas the intervening maxima have a large range in thickness (mean = 1.20 mm, s.d. = 0.47 mm). Other features include the occurrence of multiple peaks for certain maxima (Fig. 2a), the very minor 'spikes' within some ~12-yr VT minima (Fig. 2a, b), and the common

Fig. 2 Thicknesses of varves, extracted from the detailed sequence. (True thicknesses shown, obtained by dividing measurements from photographic images by 4.4.) Varve number increases up-sequence. *a*, Thick varves producing high-amplitude cycles with multiple peaks. A minor 'spike' occurs within a thickness minimum at varve 620. *b*, Thin varves producing low-amplitude cycles that display alternate higher and lower maxima. *c*, Small-scale plot showing long-term modulation of varve-cycle amplitude. *d*, Varve thickness for the entire detailed sequence (smoothed by 111-point filter), and variation with time in the period of the ~12-yr VT cycle measured between thickness minima (smoothed by five-point filter) for the same stratigraphical interval.

occurrence of alternating cycles of high and low maxima (Fig. 2b, c). In addition, regular fluctuations in the amplitude of the ~12-yr VT cycles and in varve thickness define longer periods of up to ~26 cycles (Fig. 2c, d).

The smoothed plot of cycle period against time (Fig. 2d) indicates that the long-term variation in cycle period is non-random; cycle periods are modulated by a longer rhythm with a mean period of about 13 cycles. Figure 2d shows that the thickest varves tend to coincide with relatively short cycle periods. Such negative correlation means that stronger ('higher') varve cycles tend to be of shorter duration than average. (This explains the early estimate of ~11 yr VT for the mean cycle period^{1,2}, as outcrop specimens displaying thicker, more easily counted varves and cycles were selected for examination first.) **Long sequence.** The excellent correlations obtained among the three drill holes indicate that a high level of confidence can be placed in the composite log of 1,580 ~12-yr VT cycles. Figure 3 shows the plot of cycle thickness against time for the interval of 110 cycles covered by the varve-thickness measurements, which is representative of the full sequence of 1,580 cycles.

Maxima in ~12-yr VT-cycle thicknesses occur on average every 26.2 cycles or ~314 yr VT (Table 1b). This long cycle, termed here the 'Elatina cycle', is repeated 59 times in the measured sequence. Second-order peaks that occur consistently in the same position relative to the maxima of the Elatina cycle

Fig. 3 Thicknesses of 110 ~12-yr VT cycles, extracted from the long sequence. Cycle number increases up-sequence. *a*, Cycle thicknesses showing distinct maxima every 25–27 cycles and a sawtooth pattern reflecting the characteristic alternation of relatively thick and thin cycles. *b*, Five-point smooth of the curve shown in *a*. *c*, High-frequency curve obtained by subtracting curve *b* from curve *a*. The vertical lines above the curves (*a*, *b*) mark boundaries of Elatina cycles and below the curves (*a*, *c*) positions of 180° phase reversals.

(Fig. 3b) confirm the presence of a second harmonic^{1,2} with a mean period near 13.1 ~12-yr VT cycles (~157 yr VT).

Superimposed on the Elatina cycle is a sawtooth pattern resulting from the alteration of relatively thick and thin ~12-yr VT cycles (Fig. 1b). The high frequency curve (Fig. 3c) reveals that the sawtooth pattern comprises a succession of envelopes displaying 180° phase reversals at or near the 'necks' between envelopes. A total of 106 such phase reversals occurs in the measured sequence; the interval between reversals averages 14.6 ~12-yr VT cycles (s.d. = 2.2, range = 9–23). The phase reversal is evidently a quasi-periodic function and no long-term modulation of the interval between reversals is apparent. The overall sawtooth pattern with phase reversals is described mathematically as a beat between two oscillations with periods near two cycles. As the mean period for a 360° change of phase (29.2 ~12-yr VT cycles or ~350 yr VT) is longer than the mean period of the Elatina cycle (26.2 cycles), the positions of phase reversals gradually advance up-sequence relative to amplitude maxima. The structure of amplitude maxima, therefore, varies according to their position relative to that of envelopes and necks of the sawtooth curve (Fig. 3a). As any miscount would break the observed pattern of phase reversals, the persistence of the pattern confirms the accuracy of the long sequence.

The Elatina Formation also records very long periods, notably a low-amplitude oscillation of period roughly 700–800 ~12-yr VT cycles discernible in the full plot of ~12-yr VT cycle thicknesses³.

Spectral analysis. The time series discussed above were analysed in several complementary ways: discrete Fourier transform (DFT), maximum entropy and least squares. All three methods gave similar results with regard to periods identified, although only the DFT results are discussed here. The periods determined by spectral analysis confirm those previously identified visually (Table 2), and are divisible into periods <30 yr VT, the Elatina cycle and its harmonics, and very long periods.

The DFT spectrum of the 1,337 varve-thickness measurements (Fig. 4a) reveals several discrete periods in the range of 10–14 and 22–25 yr VT, as well as longer periods of ~103, ~158 and ~333 yr VT. Additional, weaker peaks not shown in Fig. 4a occur at 8.0 and 9.7 yr VT. A beat between the periods identified at 22.4 and 25.8 yr VT may account for the beat pattern in the long sequence (Fig. 3c).

The DFT spectrum of the 1,580 ~12-yr VT cycles (Fig. 4b) reveals a striking 'harmonic series' comprising a fundamental period of 26.1 cycles and progressively higher harmonics of 13.1, 8.8, 6.6 and 5.3 cycles. Spectral plots at more detailed scales than Fig. 4b reveal two further harmonics at 4.4 and 3.8 cycles. The strong period near 2 cycles represents the ubiquitous cycle doublet. Good agreement exists between mutual periods identified in the detailed and long sequences, although the period of 26.1 cycles (Fig. 4b) is better resolved than the equivalent period of ~333 yr VT (Fig. 4a), which is beyond the limit of accurate resolution for the detailed sequence. Indeed, the consistency between data for the two sequences argues for the overall accuracy of the detailed sequence.

The Elatina cycle comprises, in accord with Fourier series expansion, a fundamental frequency and a number of higher harmonics (in the present case, six) of that fundamental. The DFT power spectral density amplitudes (*A*) of the Fourier series coefficients define an exponential function which is approximated by the equation

$$A \approx 220 \exp(-0.8f)$$

where *f* is the harmonic number (C. J. Durrant, personal communication). The harmonic series is also represented in the spectra of the detailed sequence (Fig. 4a).

DFT of the low-frequency portion of the long sequence suggests very long periods around 134, 195 and 778 ~12-yr VT cycles (~1,600, ~2,340 and ~9,330 yr VT respectively). The longest period is consistent with the low-amplitude oscillation discernible in the data³ but, statistically, is of uncertain significance in view of the relatively short record analysed.

As noted earlier, the period of the ~12-yr VT cycle appears to be modulated by a period near 13 cycles (Fig. 2d). DFT of cycle period versus time indicates that the period of the ~12-yr VT cycle is modulated principally by a period of 13.6 ~12-yr VT cycles (relative power spectral density = 1.00) and to a lesser degree by periods of 2.2 (0.73), 3.7 (0.18) and 27.8 (0.18) cycles (the latter period is, however, beyond the limit of accurate resolution). The periods of about 27.8 and 13.6 ~12-yr VT cycles may be equated respectively with the fundamental and second harmonic of the 'harmonic series' in the amplitude spectrum. Although the fundamental harmonic predominates in modulating ~12-yr VT-cycle amplitude, it is the second harmonic that

Fig. 4 DFT spectra normalized to unity for the strongest lines. *a*, DFT of 1,337 varve-thickness measurements. Spectrum unsmoothed. Linear frequency scale. *b*, DFT of thickness measurements of 1,580 ~12-yr VT cycles. Spectrum unsmoothed. Linear frequency scale. Peaks for the first to fifth harmonic of the ($26 \times \sim 12$ -yr VT) Elatina cycle are discernible.

predominates in modulating cycle frequency. The period near 2 cycles reflects a tendency for cycles of short duration to alternate with cycles of long duration, although such alternation in period shows no systematic relation to the amplitude alternation of the ~12-yr VT cycle (Fig. 3c).

Discussion

The periods recorded by the Elatina Formation cannot be explained by endogenetic processes within a glaciolacustrine system¹. Similar cyclicity has now been observed in penecontemporaneous lacustrine deposits up to 400 km from Pichi Richi Pass, indicating widespread climatic control of sedimentation. The new data generated by study of the drill cores support earlier conclusions^{1,2}, based on the study of limited outcrop, that the recorded climatic periods ultimately reflect solar variability.

The Elatina periods of 10–14, 22–25 and ~105 yr VT may be equated with cycles in the sunspot record, which similarly comprise several discrete periods between 8 and 13 yr, the Hale cycle of ~22 yr, and a longer period between 90 and 110 yr (refs 7–9). The longer Elatina periods of ~157 and ~314 yr VT are comparable to solar and climatic periods for Holocene time as indicated by tree-ring studies^{2,10,11}. The very long periods of up to ~9,300 yr VT may reflect very long-term climatic oscillations; possible counterparts exist in the recent climatic record^{12,13}, although a solar connection for such periods is not established.

The plot of varve thickness against time (Fig. 2) is comparable to that of mean annual sunspot number since AD 1700, particularly the reliable record since about AD 1830. Cycles in both the varve and sunspot series display a wide range of periods (8–16 yr VT for the Elatina Formation, 9.0–13.6 yr between minima and 7.3–17.1 yr between maxima for sunspot cycles¹⁴). The structure of cycles in each series is also comparable: minima fall to approximately the same level whereas maxima display a wide range of values; alternating cycles of high and low maxima are common; and varve cycles display an overall tendency to positive skewness, a feature also displayed by sunspot cycles^{15,16}. Furthermore, some varve-cycle maxima have multiple peaks, and minor 'spikes' occur within some minima; comparable features are displayed by the plot of mean annual sunspot (umbral) areas since AD 1920 (ref. 15). The similarity of structure of varve and solar cycles argues for a direct connection between varve thickness and solar activity, a conclusion reached previously on the evidence of overall skewness of a limited sample of varve cycles and the close similarity of portions of the varve-

cycle thickness curve to the plot of annual mean sunspot number at maxima^{1,2}. Varve-cycle structure would be quite dissimilar for an inverse relation between varve thickness and sunspot number.

The frequency modulation of the ~12-yr VT cycle (Fig. 2d) militates against the graded laminae representing monthly tidal increments, as such modulation is incompatible with regular tidal periods; indeed, the Elatina periodicities afford no evidence of tidal influence on sedimentation. Interestingly, the duration of the sunspot cycle over the reliable portion of the solar record since AD 1830 appears modulated by a longer period¹⁶, most minimum-to-minimum cycle lengths last century grouping around 11.5 yr and this century near 10–10.5 yr. A further similarity between the Elatina and solar records is the tendency for cycle duration to vary inversely with cycle amplitude. In the Elatina record, stronger ~12-yr VT cycles tend to be of shorter than average duration (Fig. 2d), and sunspot cycles of large amplitude tend to be of short duration, and vice versa¹⁷.

Portions of the plot of ~12-yr VT cycle thicknesses may be compared with the reliable sunspot record since AD 1830. Similarities include the structure of certain Elatina cycle ($26 \times \sim 12$ -yr VT) amplitude maxima and that of the solar maximum culminating in AD 1957, and the sawtooth pattern of cycle amplitudes (which maintains phase across the AD 1957 solar maximum). Such similarities between the Elatina and solar series are evident in Fig. 5. Cross-correlation between the overlapping portions of the curves shown in Fig. 5 yields the highly significant correlation coefficients (Pearson) of 0.95 (curves *a* and *b*) and 0.93 (curves *a* and *c*). That only the reliable portion of the sunspot record may be compared in this way with part of the Elatina curve increases confidence that the Elatina Formation indeed records solar variability.

Overall, the evidence from both the Elatina detailed and long sequences supports earlier conclusions^{1,2} of a direct connection between solar variability, climatic temperature change, and varve-thickness cyclicity during the Marinoan Glaciation in South Australia. In other words, increase in solar activity caused a corresponding increase in climatic temperature that resulted in greater annual meltwater discharge and the deposition of thicker varves. Importantly, recent varves deposited in glacial Skilak Lake in Alaska⁶ reveal a relatively weak solar signal recorded in this way¹⁸. Nonetheless, solar influence on climate must have been much greater during deposition of the Elatina Formation than is evident now. The composition of the late Precambrian atmosphere¹⁹ probably differed greatly from that

Fig. 5 Comparison of amplitude curves for ~12-yr VT cycles and sunspot cycles. *a*, Mean of five amplitude peaks from the Elatina long sequence (centred around cycles 89, 176, 855, 1,196 and 1,250) across which the phase of the sawtooth pattern is maintained. (A 'mean peak' was determined to reduce random noise in the geological data.) *b*, Total annual mean sunspot number for sunspot cycles since AD 1830. *c*, Annual mean sunspot number *R* at maxima of sunspot cycles since AD 1830.

of today, however, and the global climate may then have been much more sensitive to solar variability than is now observed³.

The Elatina record, in view of its clarity and great length, accordingly may provide invaluable data on which to model the physics of the solar activity cycle^{3,17}. The implications of these new data for solar physics and planetary science will be addressed separately.

G.E.W. thanks the Trustees of the CSIRO Science and Industry Endowment Fund for sponsoring the diamond drilling

of the Elatina Formation; Dr W. Robinson, Director, Laboratory of Tree-Ring Research, University of Arizona, for a temporary appointment and valuable assistance; and the National Solar Observatory, Tucson, for a visiting scientist appointment. Helpful discussions on various aspects of the work were held with Drs L. Cram, R. Loughhead, C. Durrant, W. Livingston, J. Goad, R. Jokipii, A. Skumanich, R. Bracewell, N. Alley and C. Farrelly. T. Trebisky was responsible for much of the programming. The research was in part supported by the NSF.

Thermally induced residual topography within oceanic lithosphere

Garry D. Karner

Department of Geological Sciences, University of Durham, Durham DH1 3LE, UK

The lithosphere, following a thermal event, should subside isostatically to its pre-event configuration. However, if the thermal event is sufficient to reset the rigidity of the lithosphere, then the subsidence is forced to follow a different path to the initial uplift; lithospheric rigidity decrease during uplift allows flexural deformation resetting, while during subsidence, an increasing rigidity with time results in flexural interference. This 'thermo-mechanical hysteresis' effect may be responsible for anomalous bathymetry and free-air gravity anomalies associated with hotspot traces, extinct spreading centres and the ocean/continent boundary of rifted (passive continental) margins.

BROAD-SCALE reheating of the lithosphere is the result of thermal processes such as hotspot volcanism, rifting and possibly small-scale mantle convection. Concomitant with thermal modification of the lithosphere is its isostatic uplift and mechanical weakening (rigidity decrease). The actual uplift topography is a function of only the minimum rigidity obtained during heating. Subsequent cooling of the lithosphere allows its subsidence and mechanical recovery (increasing flexural rigidity with time). However, in marked contrast to the uplift, the cumulative subsidence is a function of the entire mechanical recovery history of the lithosphere. Flexural interference between this cumulative uplift and the initial topography produces a residual topography, the amplitude and wavelength of which critically depends on the rate of mechanical recovery and the degree of lithospheric heating.
